THURSDAY, MAY 5, 1904.

THE METALLURGY OF STEEL.

The Metallurgy of Steel. By F. W. Harbord, A.R.S.M., F.I.C. With a Section on the Mechanical Treatment of Steel by J. W. Hall, A.M.Inst.C.E. Pp. xxiv+758. (London: Charles Griffin and Co., Ltd.) Price 25s. net.

A PONDEROUS volume, profusely illustrated, abounding in detail, probably the best yet published on the whole subject, yet a little disappointing, for, though necessarily to a large extent a compilation, it lacks more than need be that personal touch of the author in selection and presentation which the student so much appreciates. Such is the feeling left by a careful reading of the work. The subject is taken in four parts:—(1) the manufacture of steel; (2) reheating; (3) the mechanical treatment of steel; (4) finished steel. It inspires confidence that the author as a metallurgist has induced the well known metallurgical engineer, Mr. J. W. Hall, to write part iii., and to join with him in the chapter on reheating.

The Bessemer processes, acid and basic, and all their modifications are very well described, and illustrations of various historically interesting as well as typical modern forms of converter are given, in many cases as working drawings with dimensions. The small converters for surface blowing have a special chapter to themselves, and the best known forms are described. It is well that it is so, for they bid fair to revive a little the fading glories of the Bessemer process by their suitability for the making of steel for castings.

The general scheme adopted is to describe the apparatus, then the process, next the reactions of the process, and lastly the thermochemistry, a method which involves some repetition but makes reference easy. The open hearth is similarly treated, such special furnaces as the Siemens new form, the Campbell, and the Wellman tilting furnaces being illustrated in great detail by means of folding plates.

The somewhat sensational Talbot process is carefully considered with the author's special facilities for exact knowledge in this matter. The chapter on steel castings is disappointing, and will serve to illustrate the feeling mentioned above. Few will admit that the beneficial effect of silicon and manganese on castings is due to their removing oxidising gases, or that aluminium in the quantities used increases the fluidity or removes the dissolved oxide of iron. The statement that annealing hard castings counteracts their tendency to fly when cooling is obscure, while the full table of Prof. Arnold's recent results on castings is given without any warning that these results are the basis of a research series, and that the steels are not suitable for commercial work, a point most clearly stated in the original. The weight of Prof. Arnold's authority on practical matters, combined with the relative space taken up by the table, will certainly tend to mislead the student here. The chapter finishes with three tables of three, two and two tests respectively, showing the effect of annealing, &c., yet from a remark in the text, the last two appear to be forgings.

The chapter on crucible steel is difficult to estimate, as to anyone acquainted with the innermost workings of the old crucible steel trade, with its meagre literature, it is almost impossible to judge as to how much a writer might reasonably be expected to know. To the general reader it will be sufficiently interesting, while the beginner in a works could point out many flaws. On entering the gate on a morning the author would find that blister bar is not "cut up," but broken with a hand hammer, giving out quite a musical series of notes as the bars become shorter. The crucible shown would be difficult of manipulation by "the teemer," the real "Sheffield pot" having a well designed and quite artistic shape. The sulphur does increase in melting, and a careful watch must be kept on the quality of the coke, or the rise will be serious, even in high carbon steels, where the carbon, according to the author, expels the sulphur, which somehow in practice it fails to do. The increase of phosphorus, if any, is not detected in ordinary working.

In part iii., on the mechanical treatment of steel, by Mr. J. W. Hall, the excursions into theoretical matters of pure metallurgy are not always happy, but the other parts are treated as one would expect from an engineer of his enthusiasm and experience. The development of various types of mills, examples of modern plant, forging by the hammer and by the press, all seem excellently treated, while the case for and against fluid compression is made very clear. Several Sheffield firms, however, make high speed steels, generally acknowledged to be much more than "nearly equal to those at Bethlehem."

Part iv., by Mr. Harbord, on finished steel, treats of the metal steel itself, its mechanical properties, the relations of iron and carbon, influence of other elements, effect of heat treatment, and the microscopical examination of steel. Mechanical testing makes a good chapter, but why use the erroneous term "tensile strain" instead of "maximum stress"?

To the chapter on iron and carbon many will eagerly turn, because of the paramount importance of the subject in everyday work, its great historical interest, and it may be also because of recent controversy. Perhaps, therefore, one expects too much, but it must be confessed that the author does not seem to have risen to the occasion, and gives only a not too excellent compilation where one expected a sorting out and a grappling with the question. The well known diamond and iron *in vacuo* experiment is taken as proof that carbon can be transferred to iron without the intervention of gas, whereas it is now well known that steel which has ceased to give off gas even at 1000° C. will give off more if heated to 1200° C. After a description of temper (or annealing) carbon, "the existence of this form of carbon has not been confirmed by other investigators" is a rather startling statement. The research on "The Influence of Carbon on Iron," published by Prof. Arnold in 1895, and acknowledged by all to be a classic, is quoted, and with it some recent work of the author's own which only seems to obscure the subject. The author hardly deals fairly with his readers in withholding the tests of his steels as received, and the first three are given here (see sixth report Alloys Research Committee) side by side with ordinary commercial samples taken at random. It will be clear that they are a very undesirable series as a basis for such a research. The three numbers represent maximum stress in tons per square inch, elongation per cent. on two inches, and reduction of area per cent. respectively:—

Harbord ...	30	20	35	Harbord ...	33	13	25
Commercial	30	30	60	Commercial	35	28	47
Harbord ...	31	13	30	Harbord ...	37	6·3	19

The author seems almost alone at the present date in the opinion that "hardening carbon is possibly merely free carbon dissolved in iron," as even Stansfield, Osmond and Stead all favour the idea of carbide dissolved in iron, and the author ought to have told his readers this. He also says that the carbon theory does not explain the critical points in pure iron and loss of magnetism, but surely he must know that the main function of the carbon theory is to explain the hardening of steel. He is hardly up to date on some important matters, as he takes Arnold's mere suggestion of long ago as to Ar_3, and leaves the student to think that this is the present well defined position, whereas both sides are agreed as to Ar_1 being the real carbon change point, and to carbonists it represents the formation or decomposition of a substance corresponding to the formula $Fe_{24}C$. All are agreed also that the purest iron shows Ar_3 and Ar_2, and Prof. Arnold's theory with regard to Ar_2 is quite sufficient to account for the disappearance of magnetism. The author should remember that the serious question is this, "Does a flint hard allotropic iron exist?" The allotropists are more happy than the carbonists in that they have a crisp explanation for Ar_3, if the use of another Greek letter as a prefix can be said to give satisfaction to any practical worker in the field. The solution theory is given in detail, but the author wisely dismisses the application of the phase rule to the problems of steel by reference to original papers, and the student who endeavours to follow these is in need of sympathy if he be well acquainted with the known facts.

The extremely difficult subject of the influence of various elements on steels is well considered, but the author implies that Le Chatelier was the pioneer in our knowledge of sulphide in steel, while everyone should know that that honour belongs to Prof. Arnold. Heat treatment of steel is discussed in twenty-seven pages, and the last chapter deals with the microscopical examination of steel, and several methods of preparation and etching are well described, but Fig. 448 should either be altered to suit opaque objects or removed.

The volume closes with 100 photomicrographs, four useful appendices, and a good index. The structures shown in several of the photomicrographs are not in accord with the writer's experience, but that might be due to abnormal crystallisation in the original steels, which seem to be identical with those used for the sixth report already mentioned. Several errors have been noted, but there is only room to indicate a few as examples:—p. 53, "wild metal which pipes in the moulds"; p. 101, incorrect definition of a heat unit; p. 227, the hardening power of liquids is said to be a function of their specific heats, whereas their conductivities are more important, as witness mercury compared with water; "microphotograph" all through the work instead of photomicrograph. On p. 680 0·8 carbon steel is indicated as saturated, while on p. 681 it is 0·9, and the footnote to p. 684, "The latest research has shown that it should be 0·9," gives a wrong impression. It had no need to be shown after 1895, as Arnold made it quite clear then, and others, perhaps working on impure steels, claimed 0·8, but now they have seen their error and 0·9 is accepted almost universally. On the whole, however, the book is to be recommended as the best available on the metallurgy of steel.

A. McWILLIAM.

FROM THE ANGLER'S POINT OF VIEW.

Trout Fishing. By W. Earl Hodgson. Pp. xviii + 276. (London: A. and C. Black, 1904.) Price 7s. 6d. net.

Fishing Holidays. By Stephen Gwynn. Pp. ix + 299. (London: Macmillan and Co., Ltd., 1904.) Price 7s. 6d. net.

An Angler's Year. By Charles S. Patterson. Pp. xii + 192. (London: W. R. Russell and Co., Ltd., n.d.) Price 2s. 6d.

THE first two of these books are not in any sense books of reference or guides for the angler; Mr. Gwynn frankly states that his object is not instruction but amusement, but it is no ground of complaint that the former as well as the latter is to be found in his descriptions of his fishing holidays. Mr. Hodgson's is a pleasantly trivial book, interesting as giving the views of an experienced fisherman on many points, but no more instructive, in fact, than Mr. Gwynn's in intention. The former is at his best when describing matters of his own observation; "the whustler" would take a lot of beating as a piece of pure narrative, and is almost on a level with Mr. Gwynn's best; it calls for equal admiration in the vigour with which an almost Homeric battle is described, and the delicacy with which a veil is drawn over the undignified end of a noble fish, but it is scarcely possible to extend this admiration to the delicacy with which twenty-one of the author's friends and a daily newspaper are veiled in the obscurity of initialled dashes, which are frequently inadequate as a disguise and always typographically unsightly.

Mr. Hodgson deserves great praise for his effort to figure adequately in colours a series of trout flies, and the result is really very pleasing; we wish we could add really successful, but it seems very doubtful whether the three-colour process is suited to this class of work; the reds, and especially the clarets, are not satisfactory, and a comparison of the different representations given of, *e.g.*, the cow-dung, olive dun, or black gnat seems to show that sufficient accuracy for work of this nature cannot be obtained by the process employed. The excellent reproduction of a picture of a group of brown trout given as a frontispiece may almost serve as a contrast to the figures of flies to show the class of subjects well and ill suited for illustration by this method. It would have been interesting to have had more explanation in the book itself of the flies figured and the reasons for their selection, especially from so ardent an advocate of the wet fly as Mr. Hodgson.

Mr. Gwynn's book is most delightful; we have read much of it before in various periodicals, but nothing is lost in reading it again in book form, and the print and general get-up are so good as to give an additional pleasure to the reader. The proverb which Micky applied to the author's efforts to catch a salmon to misquote it—*Is fada do leabhar gan bradan,* cannot in any sense be applied to his efforts to write a book; it is the book that is too short, and there is a wonderful store of really useful information not only as to salmon, but as to trout and, in one excellent essay, pilchards.

Unlike Mr. Hodgson's book, Mr. Patterson's "An Angler's Year" contains a large amount of information which should be of the greatest assistance to the beginner. The method by which the author deals with his subject is good; he selects typical days from each month in the year (except March, which he not unfairly regards as "the silly season of angling"), and describes actual experiences of his own, illustrating them with information as to the best gear and method of using it in each instance. Without ever becoming didactic, Mr. Patterson gives a great deal of most useful advice upon many forms of fishing, and is equally interesting whether he treats of trout or conger. There is one addition which would, we think, be appreciated in any future edition, and that is an index, and it really seems an undue economy of space to print advertisements on the back of the title-page and table of contents; still, these are but details (as is the quaint misprint which causes the pike to figure as *Essex lucius*), and in no way affect the value of what appears to us a very practical and useful little book.

It has lately been suggested that there is nowadays too great a tendency to attribute human characteristics to animals; the fisherman certainly tends to attribute them to fish; Mr. Patterson expresses a conviction that the Test trout know more than the anglers; Mr. Hodgson combats at some length the views of those who hold that trout are cunning; both are at issue with Sir Herbert Maxwell as to a trout's sense of colour. The task of approaching the presumed feelings of a fish—especially with a view to deceive—without attributing to it some almost human qualities, even as Mr. Patterson attributes the cunning of the carp to the size of its brain and the fulness of its years, is not easy; there is a tendency almost automatically to put oneself in the place of the fish and to try to look at the world from that standpoint, and to do this one must, to some degree, give the fish human views. Our fish are certainly more interesting a little humanised, and one can feel a real sympathy for M. Guitel's goby and his efforts to find a mate which a mere bald narrative of facts would not evoke; but in reading books on fishing one cannot help wondering whether it is really the fish or only the fisherman who likes some peculiarly compounded paste or some particular tying of a favourite fly. Somehow, while feeling sure that Mr. Gwynn and Mr. Hodgson are right in insisting on the importance of the size of fly used, we yet feel some suspicion that it is the former author and not the fish he angled for that had no taste for worms.

L. W. B.

OUR BOOK SHELF.

Betrachtungen über das Wesen der Lebenserscheinungen. Ein Beitrag zum Begriff des Protoplasmas. By Prof. R. Neumeister. Pp. iv + 107. (Jena: Gustav Fischer, 1903.) Price 2 marks.

THIS is an essay—critical and constructive—on the mechanical and vitalistic interpretations of the phenomena of life. Biology has oscillated from the one position to the other since the days of Harvey. Some progress in the physico-chemical analysis of an abstracted part or process of the organism is made, and

hope rises in the biologist's breast that the secret of life is going to be discovered. Always, however, residual phenomena are detected, and there is a retreat to some form of vitalism. Prof. Neumeister gives a scholarly survey of the history, expounding the positions of Johannes Müller, Von Baer, Lotze, Du Bois-Reymond, Fechner, Wundt, Bunge, and many more. His own position, which closely resembles that of Johannes Müller, may be briefly stated as follows:—Truly vital phenomena cannot be interpreted in terms of physico-chemical categories; life is an inter-relation of the physical and the psychical—an inseparable, unknowable inter-relation; there are no forces operative in protoplasm which are not operative in non-living matter, but in all active protoplasm there are psychical qualities of a transcendental character.

Biologists will probably be most interested in the section of the book that deals with protoplasm, and the many conceptions of it that have been suggested, *e.g.* by Nägeli, Kühne, Bütschli, Pflüger, Pfeffer, Verworn, Hofmeister, Hertwig, and Ostwald. Neumeister deals at especial length with the Hofmeister-Ostwald theory, which practically reduces metabolism to a series of fermentations. As a chemical physiologist the author attacks this theory with might and main, and comes to the conclusion that ferments have really nothing to do with the essential activity of protoplasm, their activity is intracellular, not intraprotoplasmic, they are only the "chemical tools" made by and used by protoplasm. What then is protoplasm? A peculiar chemical system of very diverse protein-substances, along with certain other compounds the molecules of which by a unique interaction give rise to psychical and material processes quite inseparable from one another, in a way that we cannot hope to understand. "Ins Innere der Natur dringt kein erschaffener Geist."

J. A. T.

The Fat of the Land. The Story of an American Farm. By J. W. Streeter. Pp. xi+406. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1904.) Price 6*s.* 6*d.* net.

MANY ways have been adopted of teaching agriculture, but we do not think we have before met with an account of the management of a farm thrown into the form of a tale—a romance some readers would be unkind enough to call it. The book describes how an American doctor, warned for reasons of health to abandon a city life, purchased a neglected farm and by a liberal exercise of capital, energy and business capacity, made it both pay its way and provide him at the same time with health and pleasure, so that the family all lived on "the fat of the land." The main text is sound enough, that the farm should be regarded as a factory converting raw material into finished products and that skill and knowledge can always find a satisfactory market by the production of the best, but we doubt if the demonstration will prove convincing or even suggestive to the practical man.

The book reminds us irresistibly of the "Swiss Family Robinson," and bears about the same relation to agriculture as that friend of our childhood did to serious natural history.

Die Dissozüerung und Umwandlung chemischer Atome. By Dr. Johannes Stark. Pp. vii+57. (Braunschweig: F. Vieweg und Sohn, 1903.) Price 1.50 marks.

THIS little book from the fluent pen of Dr. Stark, of Göttingen, is a reprint of three articles in the *Naturwissenschaftliche Rundschau.* Its object is to exhibit a comprehensive view of the application of the electron theory to the group of phenomena which may be characterised as subatomic transformations, and to do this in terms which may be understood by any person of intelligence. On the whole this object is successfully accomplished.

The author shows how the discovery of Röntgen rays and of the Zeeman effect, together with the determination of the mass of the particles forming the kathode rays, have led, in the hands of J. J. Thomson, to an entire change in our ideas of atomic structure. He follows out the bearing of this idea on the phenomena of conduction in metals, in solutions and in gases, and shows how the brilliant researches of Rutherford and of Rutherford and Soddy on radioactivity led them to consider that this phenomenon was caused by the transformation of one element into others, a result which was finally established by the discovery of Ramsay and Soddy that the radium emanation turned into helium.

The book is clearly written, and its value is increased by a chapter of references at the end. It may confidently be recommended to all interested in the recent developments of physical theory.

O. W. R.

Nature's Story of the Year. By Charles A. Witchell. Pp. xii+276; illustrated. (London: T. Fisher Unwin, 1904.) Price 5*s.*

"OBSERVERS of Nature," says Mr. Witchell in his preface, "belong to one of two classes—the scientific and the imaginative." Mr. Witchell himself belongs to the latter category, for, to make use of his own words, he depicts "some curious incidents in Nature in a frame of imaginative colouring." The book will probably give readers a general interest in natural phenomena, for there is no attempt systematically to describe the plant and animal life to be found in the country at different seasons of the year. The author directs attention to anything that happens to have impressed him, and his facts and fancies are expressed in pretty terms.

Essays and Addresses. By the late John Young, M.D., Regius Professor of Natural History in the University of Glasgow. With a Memoir. Pp. xlii+145. (Glasgow: James Maclehose and Sons, 1904.)

THIS small collection of essays and addresses is issued by the committee in charge of the memorials of the late Prof. Young. The biographical sketch with which the volume commences is by Dr. Yellowlees, and it is a pleasing narrative of a well-filled life. The history of the years when Young was on the Geological Survey is particularly attractive, though throughout the narrative the reader is impressed with Young's untiring energy. The committee has selected the following essays and addresses for publication:—"Three English Medical MSS.," "A Discourse," "The Making of a Book," "The Scientific Premonitions of the Ancients," "Jewish Mediciners," and the "Address on the Hunterian Library."

The Globe Geography Readers. Senior. Our World-wide Empire. By Vincent T. Murché. Pp. 392. (London: Macmillan and Co., Ltd., 1904.) Price 2*s.* 6*d.*

THE latest of Mr. Murché's books is one of his best. It provides a simple, interesting account of the countries and peoples of the British Empire which should make the boys and girls who study it interested in different parts of the world. The volume is profusely illustrated with sixteen full-page coloured plates and an unusually large number of black and white pictures There is no rigid adherence to geographical information alone; the historical facts necessary to make up a complete description of a country are included judiciously.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Disaster to Submarine A1.

AT the inquest on the victims of the disaster to submarine A1, Commander Bacon is reported to have expressed the opinion that as the result of the collision every soul on board was instantly stunned, since the failure to set in action the mechanism for bringing the boat to the surface could not otherwise be accounted for. It is surprising that this opinion should have been received and adopted without comment by both the coroner and the lay Press, seeing that such a result is contrary to all experience of collisions at sea. The occupant of the conning tower, which was the part struck, was no doubt stunned, probably killed, by the blow, but it is difficult to believe that the same fate should have befallen every other person on board, however remote from the point of concussion.

The fact that the naval authorities can suggest no other reason for the failure to rise to the surface after the collision is not in itself a sufficient justification for the acceptance of an opinion which, from the physiological point of view, is, to say the least, highly improbable, and certainly requires confirmation by experiment.

University, Edinburgh, May 1. E. A. SCHÄFER.

The Life-history of Radium.

EVIDENCE of a convincing nature is rapidly accumulating to the effect that helium may be produced as a result of the disintegration of the radium atom. On the other hand, it has been suggested by Rutherford and others that radium is analogous to the first products of the disintegration of uranium and thorium—to the substances known as uranium X and thorium X—rather than to those elements themselves. Such an idea points to a search for the parent atom, by the dissolution of which radium is formed.

In Prof. Rutherford's recent book on radio-activity, reasons are given for suspecting that in uranium itself we shall find the origin of radium. The atomic weight of uranium is greater than that of radium. Radium is discovered in minerals rich in uranium, and the amount of radium in good pitchblende is about that to be expected on the view that a balance exists between the rate of development of the radium by the uranium present and the rate at which it decays by the ordinary process of radio-activity.

My wife and I have been investigating lately the slight amounts of radium emanation that are almost invariably found in samples of salts and oxides of uranium sold as chemically pure. By the kindness of Mr. H. J. H. Fenton we have been able to examine several specimens of uranium compounds, known to have been preserved in the Cambridge University Chemical Laboratory for periods of from seventeen to twenty-five years. In all cases greater amounts of radium emanation have been obtained from these old specimens than from more recently prepared samples of the corresponding compounds.

It is, of course, possible that a limited number of such results may be accidental, and, in order that indirect evidence of this kind should possess any weight, enough specimens must be examined to enable us to deal with the subject statistically. I should be very grateful if anyone possessing uranium compounds of known pedigree, prepared thirty years ago or upwards, would either test them quantitatively for radium emanation, or send a few grammes of them to me for examination.

If, in most cases, an excess of radium is discovered in the older samples, it would be presumptive evidence in favour of the view that radium is formed by the disintegration of uranium, but the possibility of some general change in the methods of preparation of uranium salts renders even such a confirmation of doubtful validity.

The only convincing evidence would be supplied by tracing the gradual growth of radium in a mass of a compound of uranium. At first sight, it would seem that the time required for such growth would put the possibility of such a confirmation beyond the reach of one human life. But a short calculation shows that the attempt is not so hopeless as might be imagined.

The average life of a radium atom is taken by Rutherford, on a minimum estimate, as about fifteen hundred years. The process of decay occurs in a geometrical progression, and thus in one year about half a milligramme per gramme of radium should disintegrate. On a maximum estimate for the life, the fraction disintegrated per year is 1/100 milligramme. Taking this maximum estimate as the least favourable for our purpose, we see that in one year the one hundred thousandth part will break up.

If in pitchblende, radium is in radio-active equilibrium with its source of supply, the same fraction must be replaced in the year by the disintegration of uranium. In presence of a large excess of uranium, the production of radium would go on at a constant rate. Thus in one year about the one hundred thousandth part of the proportion of radium in pitchblende would be developed in an equivalent mass of uranium.

We find that, using a good electroscope, it is easy to detect with certainty the radio-activity from the radium emanation evolved on heating a milligramme of good pitchblende. In order to produce from uranium an amount of radium large enough to detect by its radio-activity in a reasonable time—let us say one year—it is merely necessary to work with a sufficient quantity of uranium to give, in that time, a mass of radium of which the emanation has an activity equal to that evolved from a milligramme of pitchblende. The requisite quantity of uranium is clearly about $0.001 \times 100000 = 100$ grammes. This, as we said, is a maximum estimate; it is probable that less would suffice.

In this manner, by putting on one side a few hundred grammes of some compound of uranium, carefully freed from radium and tested for emanation, it should be possible to detect the growth of radium in a time measured in months, or, on the other hand, to show that it is necessary to look elsewhere for the parent atom of radium.

At the present time we have such an investigation in progress, and trust that eventually we may obtain definite results. But, in the hope that others may undertake a similar task, I venture to place the principles of the method before your readers. On such a fundamental point, several independent experiments are greatly to be desired.

W. C. D. WHETHAM.

Upwater Lodge, Cambridge, April 30.

Graphic Methods in an Educational Course on Mechanics.

THOUGH no one, I venture to think, will gainsay Mr. W. Larden's main contention that "analytical methods give a grasp of the principles of statics, while graphical methods disguise them," yet it should not be forgotten that the analytical treatment has its own set of snares and pitfalls.

Mechanics is a physical science, and like other sciences should be approached from the experimental side. If the initial stages are treated experimentally, the principles underlying the subject will come prominently into view. One need only mention the principle of moments, which every boy has surely grasped, in a general sort of way, long before he has opened a text-book on statics. He has only to carry out a few simple experiments on levers to find out the law for himself in its exact form. Let the beginner hang up two spring balances from nails and then attach a weight by a couple of strings to the hooks of the balances, and he will soon discover for himself whether or not the pulls in the strings are proportional to their lengths.

The graphical treatment lays stress on the empirical and tentative side, which in the symbolical is completely lost sight of. But the superlative advantage of graphical work is its essentially practical character. All cases of a problem can be solved with equal facility. Ladders are not as a rule inclined to the ground at an angle of 60°, coefficients of friction are never quadratic surds, and weights of $\sqrt{2}$ poundals belong to some other world which is not the one in which we live. Again, the question is on a screw jack, and a boy taking $\pi = 22/7$ has worked out an answer

to four or five significant figures, and in consequence expects to get greater credit than his more indolent neighbour who has been content with two or three significant figures. Instances might be multiplied; they constitute the daily purgatory of every teacher. Something surely is to be said for a method which avoids these absurdities.

Analytical methods have so dominated the elementary text-book that many boys have the idea that statics is practically useless. They have no notion, for instance, that graphic statics lies at the foundation of bridge construction. Besides, in how many questions in the elementary text-book is the principle involved wholly obscured, because a trigonometrical conundrum is required and not an application of the conditions of equilibrium to give the unknown forces? In a popular text-book one-third of the questions at the end of one of the chapters are of this character. Is it to be wondered at that the average boy gets the idea that mechanics is a subtle epilogue to trigonometry?

Each question treated graphically should be regarded in the light of an experiment, in which the student should get the best result available with the means at his disposal. In any actual problem the *data* themselves are not correctly known, and the *quaesita* are therefore subject to all sorts of cumulative errors. This he quickly finds out by comparing his result with that of his neighbour, and he readily gets a notion of the degree of accuracy that he himself with pencil and ruler is capable of.

Mr. Larden writes:—"a student well trained in analytical methods can always pick up graphical methods rapidly when he needs them for special work." But will he do so? The engineer is not trained in analysis and allowed to adopt a graphical method when a specific problem arises. My experience is that the student, who has mastered analytical methods, is apt to consider graphical work as drudgery, and when called upon to solve a question graphically does not treat it with sufficient respect, and gets an indifferent result. A certain amount of finesse and judgment in choice of scale and of position of the initial force or load is required "to fit the diagram on to a given sheet of paper." This can be acquired only by practice.

Unfortunately it is too true that "graphical work consumes an amount of time that seems out of proportion to the mental training and knowledge of principles gained," but only when applied to too many similar questions. This, however, is misusing, not using the method.

I believe the best results will be obtained when the two methods are used side by side. They are strictly complementary, and the merits of each supply the deficiencies of the other. R. M. Milne.

R.M. Academy, Woolwich.

Asser and the Solar Eclipse of October 29, 878.

Under the date DCCCLXXIX, Asser, in his "Life of King Alfred," gives the following entry:—"*Eodem anno eclipsis solis inter nonam et vesperam, sed proprius ad nonam, facta est.*" The oldest manuscript of the Anglo-Saxon Chronicle also notes an eclipse in 879, but it cannot be doubted that in each case the reference is to the eclipse of October 29, 878, which was total in South Wales and southern England. Particulars of the eclipse are given by Mr. Maguire in the *Notices* of the Astronomical Society, vols. xlv., 400, and xlvi., 26. The sun rose totally eclipsed in 73° N. and 42° 8′ W. at about 9.53 local time, and the central line of the eclipse, after passing near Dublin, Aberystwith, Dover and Fulda, went off the earth at sunset about 130 miles south of Moscow at 4.20 local time; St. David's, Winchester and London were within the limits of totality. With regard to the hour of the eclipse, it is needful to consider not only mean time and apparent time, but also natural time, which was the kind of time then in use, according to which the period between sunrise and sunset was conceived to be divided into twelve hours, which were, of course, much shorter in winter than in summer. As the sun rose at London on the day of the eclipse about 7.20, the natural hour would have contained only about 47 minutes of mean time. Mr. Maguire gives the middle of the eclipse at St. David's about 1.12, and at London about 1.18 mean time, and subtracting the equation of time, about 15 minutes, we have 12.57 and 1.3 for the apparent time as shown by a sundial; correcting for natural time, we obtain 1.13 for St. David's and 1.20 for London. Finally, making allowance for the difference of longitude, we see that totality occurred at St. David's at 12.46, and at London at 1.20, according to local time as shown by a waterclock, or some other time-keeper, properly regulated to mark the natural hours. We now have to consider what Asser meant by *Nonam* and *Vesperam*. Those who have written about the passage have taken *Nonam* to be identical with *Nonam Horam*, but probably they have not been right in doing so. It is shown in the "Dictionary of Christian Antiquities" (i. 793) that the day and night were divided into four equal parts, and that each quarter of the day was named after the last hour in it. "None embraces the seventh, eighth and ninth hours; and the last called Duodecima contains the tenth, eleventh and twelfth, ending at Sunset." Asser, however, evidently uses *Vespera* for *Duodecima*. *Nona* is, in fact, noon, the point when the sun is on the meridian, the beginning of the seventh hour, and *Vespera* is the point half-way between noon and sunset, in this case 2.20 mean time and 3.0 natural time. Thus what Asser says is this, that the eclipse was total at a point of time between noon and 1.30 natural time, and we see that the statement is true for any point in England or Wales. If we could be sure that the sentence about the hour of the eclipse was written by Asser of St. David's, it would be a very strong argument, indeed, for the genuineness of the book which is called by his name, for it fixes the moment of the eclipse correctly to within seventy minutes of mean time for any place at which it is possible that the book could have been written. C. S. Taylor.

Banwell Vicarage, April 23.

"Abdominal Ribs" in Lacertilia.

It is usually stated in text-books that among living reptiles only the Crocodilia and Hatteria are furnished with abdominal ribs or parasternum: that is, of course, in the condition of thin pieces of bone lying between the ventral muscles and underlying the true ribs, for no one doubts that the plastron of the Chelonia is the same structure exaggerated. There has been some little confusion between the abdominal ribs and the ventral moieties of the true ribs in Lacertilia, which is cleared up by Dr. Gadow in his contribution to the "Cambridge Natural History." Dr. Gadow correctly observes of the geckos that they possess very long and slender post-thoracic ribs, "which meet each other in the middle line, in this case bearing an extraordinary resemblance to the so-called 'abdominal ribs' of other Reptiles." The statements as to "abdominal ribs" made by M. Boulenger in his catalogue of the lizards in the British Museum appear to me to refer to true ribs. Of the Scincidæ, he remarks that "ossified abdominal ribs are absent." Curiously enough, it is precisely in this group that I find a parasternum. In *Tiliqua scincoides* the ventral musculature is divided by the usual tendinous septa into successive "myotomes," the tendinous intervals being distinctly ossified; there are several pairs of these bonelets which seem to be exactly like those of Hatteria, with which I have compared them. That they are not the ventral moieties of the true ribs is shown by the fact that they overlap the latter, the two series of structures lying at a different plane in the musculature. I intend to make a more detailed communication to the Zoological Society upon this subject immediately. Frank E. Beddard.

Inheritance of Acquired Characters.

Regarding the "non-inheritance of acquired characters," the following is interesting:—

I was recently visiting a sugar plantation near Ottawa, Natal, and there was shown four fox terrier pups about a fortnight or three weeks old, two of which had been born with quite short tails, and one with a tail shorter than the normal. The fourth pup had a full-length tail. The mother was an ordinary fox terrier with cut tail. When the circumstance of these dogs being born with short tails was first mentioned to me I refused to believe it; but examination showed that the short tails were really naturally short tails and not tails that had been cut, that is to say, the short tails had at their ends the usual tapering vertebræ of a normal dog's tail, and, of course, at this age it was easy to see that the tails had not been cut or bitten off.

Cape Town, April 7. D. E. Hutchins.

THE POPULARISATION OF ETHNOLOGICAL MUSEUMS.

SPEAKING broadly, museums may be divided into two main classes, (1) those that are designed to interest and instruct the general public, and (2) those that are intended for specialists. Difficulties and misunderstandings arise when these two objects are not kept apart. The casual visitor is impressed, but scarcely edified, by long series of named specimens, and the specialist does not need popular descriptive labels, but he does require a large number of specimens. The problem that is now before most of our large museums is the conflict of these two interests. Probably the most satisfactory solution will be found in keeping these two classes of collections quite apart. Dr. F. A. Bather, in his suggestive and practical presidential address to the Museums Association (*Museums Journal*, vol. iii., 1903, pp. 71, 110), said, "the functions of museums are three: Investigation, Instruction and Inspiration appealing respectively to the Specialist, the Student, and the Man in the Street. These functions are so distinct that they are best carried out if museums, or the collections of a single museum, be classified on these lines. Such an arrangement is a saving of trouble and expense, and each division can thus be directly adapted to the class of visitors for which it is intended."

The specialist needs all the specimens he can get in a building where they can be safely housed and be readily accessible; he asks for facilities, not for architecture. If once this were fully realised a considerable amount of unnecessary expenditure could be saved. There are many objects that should be preserved for future generations which are neglected by museum curators because they cannot afford to store them, but there would be less excuse for this neglect if the cost of storage could be greatly reduced. At the Liverpool meeting of the British Association Prof. Flinders Petrie advocated the erection of a repository for preserving anthropological or other objects; an outline of his scheme was published in the *Report*, 1896, p. 935, and to the present writer it appears that something of the kind will have to be adopted by most countries, and the sooner this is done the better will it be for science, as objects that should be preserved are continually perishing or are discarded from lack of space in which to house them.

The general public provides most of the funds for the establishment and maintenance of museums, and it may very well insist on having something for its money that it can understand. A museum can be made into an institution of very great educational value without loss of attractiveness if some trouble be taken and if funds are available, and it is very probable that funds would be available if the results were such as could be appreciated by everyone. Our Natural History Museum at South Kensington has set a fine example of what can be accomplished in the way of well mounted birds in their natural surroundings. Probably lack of space and funds has prevented the authorities of the Natural History Museum from constructing large groups of mammals similar to those which form such a splendid feature of the Field Columbian Museum of Chicago, and to a less degree of the American Museum of Natural History, New York.

The pleasure and instruction afforded by the realistic mounting of groups of animals are undoubtedly very great, and not less so are those caused by analogous ethnological groups. The present writer had his first interest in ethnology awakened by the excellent modelled groups of natives in the Crystal Palace, and the wonder and delight these gave to the small boy have never been forgotten. Various museums at home and abroad possess individual figures dressed in appropriate costumes, but it is again to the United States that we have to turn for the most effective development of this art. There are several first class groups of American natives in the American Museum of Natural History, others are to be found in the Field Columbian Museum; especially noteworthy in the latter museum are the groups illustrating the

FIG. 1.—A Cocopa Indian family of the Sonoran ethnic province, Lower Colorado River, Mexico. They subsist largely by means of agriculture, feeding partly on game and fish, with various seeds, roots and fruits. They dwell in scattered settlements. The men wear skins and the women petticoats made of the inner bark of the willow.

rituals of the Hopi Pueblo Indians, to which the attention of the readers of NATURE was directed a short time ago (NATURE, vol. lxvii., p. 392), and a wonderful case illustrating the domestic industries of the Hopi. It was once the writer's good fortune to be in the company of a couple of Navaho Indians who saw these models for the first time; they could not mask the interest they felt in seeing these representations of their neighbours, and great was their delight in noticing that the model of a particular woman, whose face they recognised, had, like her original, an amputated finger.

The high-water mark at present reached in this direction is in the dozen groups of lay figures designed by Prof. W. H. Holmes, and first exhibited in the Pan-American Exposition in Buffalo, 1901, to which reference has been made in these pages, and which are now in the National Museum at Washington. These groups present in the most striking manner possible a synopsis of the American aborigines, from the

Eskimo of North Greenland to the wild tribes of Tierra del Fuego. Each lay figure group comprises from four to seven individuals, selected to convey best an idea of the various members of a typical family. The activities of the people are illustrated, and the various products of industry are, so far as possible, brought together in consistent relations with the group. No one who has seen these splendid groups can doubt that this is the best way of illustrating the more salient features of ethnology, especially when these are supplemented, as in Prof. Holmes's scheme, with models made to scale of habitations and of boats, with a limited selection of objects made by the various people, and illustrations of their more important physical characters, such as crania, casts from life, and pictures. An exhibit such as this for all the more important groups of mankind would be of extreme interest and educational value, and would meet all the requirements of the public. If this arrangement were carried out the great bulk of ethnological material, which takes up so much space in large museums, need not be exhibited to the casual visitor.

There are two methods of constructing the lay figures of ethnological groups. The one is to make casts of actual individuals, and the other is to have effigies made by a sculptor. The Chicago groups are examples of the former method, but the Washington groups were made in the following manner:—"The sculptors were required to reproduce the physical type in each instance as accurately as the available drawing and photographs would permit. Especial effort was made to give a correct impression of the group as a whole, rather than to present portraits of individuals, which can be better presented in other ways. Life masks, as ordinarily taken, convey no clear notion of the people; the mask serves chiefly to misrepresent the native countenance and disposition; besides, the individual face is not necessarily a good type of a group. Good types may, however, be worked out by the skilful artist and sculptor, who alone can adequately present these little-understood people as they really are and with reasonable unity in pose and expression."

FIG. 2.—A dwelling group of the Pawnee Indians, a type of the Missouri Valley region. The Pawnee formerly lived in Nebraska. Although their home is in the country of the skin-tent dwellers, they continue to build the ancient northern type of earth-covered aboue with slightly sunken floor.

These groups and the other ethnological exhibits prepared under the direction of Prof. Holmes are figured and described in the annual report of the U.S. National Museum for 1901, published by the Smithsonian Institution in 1903. In the same volume will be found Prof. Holmes's views on the classification and arrangement of the exhibits of an anthropological museum. This essay, which will prove of considerable value to those concerned in this class of work, was previously published in the *Journal of the Anthropological Institute* (vol. xxxii. p. 353).

In his address Dr. Bather dealt mainly with art museums, but he alluded to folk museums, and Mr. Henry Balfour, in his recent presidential address to the Anthropological Institute, advocates the establishment of a national museum to illustrate the evolution of culture in our islands; he, like Dr. Bather, instances what is done in this respect in Scandinavia and Germany. Certainly this is much needed in our country, and immediate steps should be taken to realise it; already much has irrevocably been lost, as there was no institution that cared to preserve the relics of former conditions. In the same address Mr. Balfour gives some valuable suggestions for the arrangement of ethnological museums. Mr. Balfour's address will be printed in the forthcoming number of the *Journal of the Anthropological Institute*, and it will be found to be well worth perusal, as it embodies the long experience of a well-known expert in museum arrangement. It is to be hoped that the time may not be far distant when the educational value of properly arranged ethnological museums will be recognised in this country, and the means will be found to establish them.

A. C. HADDON.

ROUND KANCHENJUNGA.[1]

THIS work of Mr. Freshfield's on a tour round Kanchenjunga comes as a very welcome addition to the literature that deals with the great mountain peaks of the world. Kanchenjunga (28,150 feet) is the third highest measured peak on the earth's surface, Mount Everest being 29,002 feet, and K^2, in the Karakoram range north of Kashmir, 28,278 feet high. At present Mount Everest is hopelessly impossible of access, being in Nepal, a country entirely closed to Europeans; K^2 also lies so far removed from civilisation that it takes weeks of travelling, many days of it over glaciers, to arrive even at its base.

Kanchenjunga, however, can be seen from Darjeeling, and the view of the peak from that place is one of the grandest sights in the world. Kanchenjunga and its attendant peaks form a solitary group of mountains, which divides the province of Sikkim from eastern Nepal, and lies far south of the watershed of the Himalaya.

It is now many years since Sir Joseph Hooker in 1848–1850 made his famous journeys into the country round Kanchenjunga, and obtained leave from the Government of Nepal to travel in the Nepalese valleys on the west and south-west of Kanchenjunga. This leave has never been repeated, and it was not until Mr. Freshfield and his party descended the glaciers on the north of Kanchenjunga and trespassed in the Kanchen valley that Englishmen again set foot in this forbidden land.

[1] "Round Kanchenjunga; a Narrative of Mountain Travel and Exploration." By Douglas W. Freshfield. With Illustrations and Maps. (London: Edward Arnold, 1903.)

Briefly summarised, Mr. Freshfield's tour was as follows:—Starting from Darjeeling he made his way up the valley of the Teesta River, which, running southward, bounds the whole of the Kanchenjunga range on its eastern side; leaving this valley the Zemu River was followed until the Zemu glacier was reached. Here it was that the party were overtaken by the great storm of September, 1899, which "after devastating Darjeeling, swept across Kanchenjunga into Tibet in the form of a premature snowfall, lowering the snow-level nearly 4000 feet and practically closing the highest region." As there was no wind the snow did not drift, but after the storm was over it lay between three and four feet deep round the tents.

Such conditions would have turned back most travellers and stopped any attempts to cross passes more than 20,000 feet high. Mr. Freshfield, however, was not discouraged, and although even a partial ascent of Kanchenjunga was out of the question, still he managed to lead the party over the northern ridge of the Kanchenjunga range and to explore some totally new ground in eastern Nepal. Before doing this he moved north-eastwards to Lhonak. It was from here that the party, together with the baggage train of coolies, crossed over the Jonsong La (20,207 feet). On the west side of this pass lay Nepal, an unknown land. For several days the route lay downwards over glaciers, and it was only after nearly a week spent on the ice and snow that the party finally arrived at the upper grazing grounds of the cattle belonging to the Nepalese village of Kangbachen. Here it was that they connected their route with that of Sir Joseph Hooker, who fifty years previously had visited this valley.

As the party were now in forbidden country, some anxiety was felt as to their reception by the inhabitants, but with the exception of one official no trouble was met with, and as an excuse for the trespass it was pointed out that, driven by the great snowstorm over the pass, the party were seeking their way back to British territory, and that obviously their nearest way was down the Kanchen valley, thence by the Chunjerma and Kang La back to Darjeeling.

From many points of view this work of Mr. Freshfield's is of interest; it is a delightful record of mountain exploration, it is splendidly illustrated, and the descriptions of ice-clad mountains, of tropical forests, and of the great beauty of the atmospheric effects in this great mountain range are all given most admirably by the author. Moreover, many most interesting scientific and geographical problems are discussed.

Fig. 1.—Camp below the Jonsong La. From "Round Kanchenjunga," by Mr. Douglas W. Freshfield.

One important question was as to whether there are peaks higher than Mount Everest lying further to the north in Tibet. Twenty years ago Mr. Graham, from the summit ridge of Kabru, at a height of more than 20,000 feet, asserted that he saw two peaks, one covered with snow and one of rock, further north than Mount Everest, and that they appeared as high, possibly higher, than Mount Everest. This statement has been partly confirmed by native explorers. That high peaks exist there is undoubted, and one was seen from the Chunjerma Pass by Mr. Freshfield. Also more recently a photograph taken by Mr. H. H. Hayden, and published in the *Geographical Journal* (1904, 362), shows these peaks. Mr. Freshfield, commenting on this photograph, says:—"Somewhat to the north-west of Chomokankar (Mt. Everest) appears a great group of peaks; one rock and one snowy

summit are conspicuous. These are apparently as yet unidentified and unmeasured. They rise at no great distance beyond Chomokankar, and are probably south of the Tingri Maidan."

During late years much has been written about the effect of rarefied air at high altitudes on the human system. Mr. Freshfield and his party suffered but little inconvenience, even when on the summit of the Jonsong La (20,207 feet). That the effects of low barometric pressure have been much exaggerated is also borne out by the experience of Mr. White, political officer in Sikkim, who says:—"I find that the height is felt most at from 14,000 to 16,000 feet, and that if they (the coolies) once get over that, going to a still higher altitude has very little further effect. Personally the height does not affect me, and I felt perfectly well at 21,200 feet."

The geology of the district is most ably described by Prof. Garwood, by whom also an excellent map of the whole Kanchenjunga range has been made.

Mrs. Le Mesurier has contributed a chapter on Tibetan curios, and in the appendix, besides the exhaustive description by Prof. Garwood of the geological structure and physical features of Sikkim, there is a mass of important and interesting matter collected by the author; on the narratives of journeys made by native surveyors; on the various native names for the highest measured peak (Mount Everest); also a most useful list of books and maps consulted, and last, but not least, a list of photographs taken by Signor V. Sella during the tour of Kanchenjunga.

"Round Kanchenjunga" is a book worth reading from many points of view; it is not merely a tale of mountaineering adventure, but is full of information, artistic description, and new facts. It is a book which undoubtedly will be "serviceable to Alpine climbers and men of science, and not without interest for those who 'love the glories of the world' and count among them great mountains."

HIGHER EDUCATION IN THE UNITED STATES.[1]

ALL intelligent attempts to make known in this country the extent and success of American educational enterprise deserve encouragement. So well considered an effort as that of Mr. Mosely not only merited but has received enthusiastic appreciation. By securing the assistance of educationists representative of successive steps in a complete educational system, Mr. Mosely has been able to bring together in convenient compass authoritative expressions of opinion as to the precise state of each grade of education in the United States, and to provide our new educational authorities with information as to the characteristics of American education which good judges think might with advantage be copied in this country. Similarly, the features of the work of schools and colleges in the States which should be discouraged among us are in this report duly indicated. Mr. Mosely has, too, made arrangements to ensure a wide circulation for the valuable material collected under his auspices. By forwarding to the publishers of the volume the cost of postage and stating his qualifications, any member of an educational authority, any county councillor, local manager, headmaster, or registered teacher may obtain a copy of the book free.

The twenty-six separate reports contained in the volume cover the whole field of education from the kindergarten to post-graduate university study, but it will be possible in this place to refer to a few only of the more important directions in which American practice offers British educationists food for serious reflection. The most prominent place may well be given to an impression received by all the commissioners alike, and recorded first in their joint report; we refer to "the absolute belief in the value of education both to the community at large and to agriculture, commerce, manufactures, and the service of the State" which distinguishes the inhabitants of all the United States. Side by side with this record of their observations must be placed the commissioners' message to their countrymen, which is expressed as a desire "to impress on the British public the absolute need of immediate preparation on our part to meet such competition" as this enthusiasm for education in America will lead us to experience. Evidence of the advances in American education, and also of the sacrifices made in the States to endow and develop colleges and universities, have been frequently laid before readers of NATURE But though here and there in Great Britain a desire has been manifested to found new universities, and though we are glad to admit that a few of our men of wealth have emulated the example common among American millionaires of giving largely to educational institutions, a general awakening on the part of the nation so far as a thorough belief in education is concerned is still a matter of the future. Meanwhile, the schools and colleges of the United States go steadily on with their work of preparing the rising generation. As Mr. W. P. Groser, who was nominated to the commission by the Parliamentary Industry Committee, says in his report, "England is now competing with American commerce in the making. In the next generation our manufacturers will meet trained men, adding culture to their enterprise and knowledge to their ambition."

Another striking difference between the English and American attitude towards education is appreciated by comparing the relations in the two countries between industry and higher scientific and technical instruction. The report makes it abundantly clear that in America there is complete sympathy between the manufacturers and the college professors, and that properly trained college men are in great demand. Says Prof. Ayrton, "I saw that there actually existed that close bond of union between the industry and the teaching which only the more sanguine of us have hoped they might, perhaps, live to see introduced into our own country." Mr. Blair asserts, "the relationship between the schools and the industries has become one of supply and demand." Prof. Ripper states, "We were frequently told that 'the American manufacturer twenty years ago, like the English of to-day, thought little of the technically trained men. The difference between us now is that the American has changed his opinion, while England appears to be where she was'" Commissioner after commissioner gives instances of the large proportion of men educated at college who are engaged in great manufacturing concerns in the States. Out of 10,000 employees in the Westinghouse shops and offices, there are 160 college-trained men employed. At the Carnegie Steel Works, where there are 7000 hands, about a hundred technically trained men are engaged, seven of the twenty-three leading officers being college graduates, and similar cases might be multiplied indefinitely.

The same enlightened policy is adopted in the matter of apprentices. Prof. Ayrton was told everywhere, "an engineering apprentice in a factory should be a college trained man," and the foreman of the apprentices at the Westinghouse works informed him, "the engineering apprentices, of whom we have about 150,

[1] "Reports of the Mosely Educational Commission to the United States of America, October–December, 1903." Pp. xxiv+400. (London: Co-operative Printing Society, Ltd., 1904.) Price 1s., post free 1s. 4d.

must be first-class graduates of leading technical schools. We start them on trial at 8*d*. an hour, and if really bright they may be earning 30*l*. a month with us at the end of eight months. We are always on the look-out for bright men; we cooperate with the professors of colleges to get them." "Two of the chiefs of the staff of the Westinghouse Company," says Prof. Ayrton later, "visit all the principal universities, colleges, and technical schools throughout the United States every year for the purpose of seeing the students, and choosing those who are most suitable to work with the Westinghouse Company." College students, too, are encouraged to work in the shops during vacation time, and in this way to supplement theoretical knowledge with practical experience.

Still another way in which the connection between the training given in the technical schools and colleges and the needs of industry is in America made intimate and real is to be found in the conditions of tenure pertaining to professorships. All the practical men engaged in engineering consulted by Prof. Ayrton were unanimous in telling him that "an engineering professor in a college should be actively engaged in the practice of his profession." Or, as he says later in his report, "engineering education in America is directed by those who are doing the engineering work of their country." Prof. Maclean's evidence is in the same direction; he states, "superior men are induced to accept collegiate appointments because of the well-equipped laboratories at their disposal, and because as engineering professors they are given every opportunity and encouragement to do outside work. It is believed that thus they keep in touch with the various lines of progress in their profession." Prof. Ripper, too, adds his testimony to the same effect. He writes, "it is considered vital that the professor should be in the field of practice, otherwise he is liable to become stale and out of date, and to attach exaggerated importance to unnecessary things."

The scepticism of the British manufacturer as to the value of a scientific training in the workshop and factory, his neglect of the technical expert, and his ingrained conservatism are already painfully familiar to men of science. It is unnecessary to insist, in view of what this latest report tells of American enlightenment, that in the absence of an earnest endeavour by British directors of industry to follow the lead of their contemporaries in the States, the results will be disastrous—indeed, fatal—to our commercial supremacy.

To turn now to the extent that science is in America utilised in the service of the State—a matter the importance of which has been urged consistently in these pages. A joint report, signed by the commissioners as a body, places it on record that "the closest connection is being established between theory and practice, the practical bent of the men of letters and science and the breadth of their outlook being very remarkable. The services of experts in various branches of knowledge are, therefore, held in high esteem and are in constant demand." And Prof. Armstrong, in a report brimful of good things, gives numerous examples of the appreciation by the American Government of the services of men of science. To quote one or two of his *obiter dicta*:—"So far as I am aware, there is nothing anywhere to compare with the way in which science is being utilised in the service of the State by the U.S. Department of Agriculture." "There is no question that the research work done under the auspices of the Agricultural Department and in the experiment stations is of the very greatest value, and is contributing most materially to the development of agricultural industry." "One branch of work initiated in the Office of Experiment Stations at Washington of extreme importance, to which reference should also be made, is that relating to the nutrition of man, which has been carried out in various parts of the States under the supervision of my friend Prof. Atwater." If it were necessary, similar examples from these reports could be multiplied a hundredfold.

In a short review it is possible only to touch the fringe of so great a subject. Much of value in the reports has been left completely on one side. But it is greatly to be desired that every man of science, every person engaged in education, whether as administrator or teacher, will study the volume. It is an important and absorbingly interesting contribution to a subject that deserves the immediate attention of every one of our statesmen.

A. T. S.

NOTES.

The annual conversazione of the Royal Society will be held on Friday, May 13.

We regret to see the announcement of the death of Prof. E. Duclaux, director of the Pasteur Institute, at sixty-three years of age.

Prof. A. W. Williamson, F.R.S., is lying dangerously ill at his residence at Haslemere.

Invitations have been issued by the Royal Society of Edinburgh to a conversazione to be held in the rooms of the society on Saturday, May 28.

Prof. Henri Becquerel, of Paris, has been elected a corresponding member of the Berlin Academy of Sciences.

The deaths are announced of Prof. Leidie (chemistry), of Paris, and Prof. Charles Soret (experimental physics), of Geneva.

In the *Physikalische Zeitschrift* for April 15, Prof. Th. Indrikson states that he has repeated Sir William Ramsay's experiments showing the spectrum of helium in the emanations from radium, the experiments being in this case conducted in the physical institute at St. Petersburg, where no experiments with helium had previously been made.

It is announced that an annual subsidy of 35,000 kr. (1950*l*.) for twenty years has been granted by the Icelandic Government for the establishment of a wireless telegraphic connection between Iceland and the Shetland Islands or the mainland of the United Kingdom, and also between the four principal towns of Iceland.

The council of the Institution of Civil Engineers has made the following awards for papers read and discussed before the institution during the past session: A Telford gold medal to Major Sir Robert Hanbury Brown, K.C.M.G., a George Stephenson gold medal to Mr. G. H. Stephens, C.M.G., and a Watt gold medal to Mr. Alphonse Steiger. Telford premiums to Mr. E. W. de Rusett, Dr. Hugh Robert Mill, Mr. Alexander Millar, and Dr. T. E. Stanton. A Manby premium to Prof. J. Campbell Brown, and a Crampton prize to Mr. L. H. Savile. The presentation of these awards, together with those for papers which have not been subject to discussion and will be announced later, will take place at the inaugural meeting of next session.

The Geologists' Association has arranged an excursion to Derbyshire for Whitsuntide. Four days are to be devoted to out-door geology. The party leaves St. Pancras for Buxton on Friday, May 20, and is expected to arrive in London from Derby on Wednesday, May 25. On Saturday, May 21, the excursion will be directed by Messrs. H. A.

Bemrose, E. Sandeman, and H. Lapworth, but for the other three days Mr. Bemrose alone will be the director. The details of the excursion seem to have been carefully planned, and full particulars of these, together with information as to special fares and hotel arrangements, can be obtained from the excursion secretary, Mr. H. Kidner, 8 Derby Road, Watford.

A circular on the present state of the trade in indigo between India and Aleppo, prepared by the reporter on economic products to the Government of India, is noted in the *Journal* of the Society of Arts. It appears that between 600 and 700 chests of indigo are imported into Aleppo from India every year. On account, however, of the competition of German synthetic indigo, this is usually sold by the merchants at a loss. This synthetic indigo has two advantages over the natural product, viz. that it is cheaper and that its price does not vary. The native dyers have found that when natural and synthetic indigo are mixed in about equal proportions, the resulting mixture is more durable and also brighter in colour than the natural indigo. On account of the impetus that has been given to the dyeing industry by the popularity of this mixed dye, much more indigo is used than formerly, and the reduction in the demand for natural indigo has not been nearly so great as might have been expected from the introduction of synthetic indigo.

We have received a copy of the results of the magnetical and meteorological observations made at the Royal Alfred Observatory, Mauritius, in the year 1900, and we note a marked improvement in the form in which the results are now presented, being on the pattern of the Greenwich observations. The routine work has been carried out in a very satisfactory and thorough manner. Photographs of the sun are taken daily, when possible, and the negatives sent to the Solar Physics Committee in London. Meteorological bulletins are supplied daily to the local Press, and copies of monthly results are forwarded to this country and elsewhere. Rainfall observations are now made at about seventy stations, and the results are duly tabulated. Special attention is also given to magnetical and seismological observations.

Mr. J. R. Sutton has contributed to the report of the South African Association for the Advancement of Science a valuable paper containing the determination of mean results from meteorological observations made at second order stations on the table land of South Africa. Observations in Cape Colony are generally made at 8h. a.m. (mean time of the colony), but at some stations other hours are used. The object of the paper is to give materials for reducing these to a common standard of reference. At the cost of a great amount of labour, the author has calculated, from the very complete observations made at Kimberley, the corrections to be applied to means for each hour for all elements in order to obtain the true mean for each month and for the year. He makes suitable reference to the work of the late Mr. Stone, who made a somewhat similar calculation from the Cape observations for 1841–6.

Dr. T. Levi Civita contributes a note to the *Atti dei Lincei* for March 20 on Kepler's equation $nt=u-e \sin u$, and the limits of convergency of the well known expansion of u in powers of e.

Some experiments by Prof. A. Stefanini and Dr. L. Magri on the influence of radium on the electric spark, communicated to the *Atti dei Lincei*, xiii. (1), 6, by Prof. Battelli, lead to the following results:—For discharges between two spheres, or between a positively charged point or sphere and negative disc, the discharge is facilitated by radium for short sparking distances and impeded for longer ones; at these distances the radium influences the positive pole. If the disc is positive and the sphere or point negative, the discharge is impeded at small sparking distances within a limited interval; in general the effect is nil. For certain sparking distances between a sphere and disc it is possible for radium to impede or facilitate discharge according to which electrode is positive.

In the April number of *Climate*, the anti-malarial campaign at Ismailia is described. Dr. Harford discusses sleeping sickness and its cause, and articles of medical interest, reviews and notes complete the contents of this useful journal.

In a pamphlet entitled "Recent Improvements in Methods for the Bacterial Treatment of Sewage" (Sanitary Publishing Co.), Mr. Dibdin describes his multiple surface bacteria beds. The basis of his thesis is that there is no need for sewage to undergo a preliminary anaërobic treatment as in the case of the septic tank process, but that aërobic action alone suffices under the proper conditions. Mr. Dibdin constructs his beds of ridged tiles or of slate débris.

In the *Bulletin* of the Johns Hopkins Hospital for February (vol. xv., No. 155), Dr. Kennon Dunham describes the effects of the Röntgen rays on lower animal life. These differed with the particular species exposed, Chilomonas and two species of Paramæcium being killed after six exposures, each of three minutes' duration on three successive days, while rotifers, Arcella and Cryptomonas were unaffected by this treatment. As regards the different rays, those having the strongest action were found to be directed from the centre of the anode plate in a line perpendicular to its face, and focused by passing through a cylinder of sheet lead. The most destructive rays were produced by a medium low tube excited by a heavy electrical discharge which had been passed across spark gaps or other resistance sufficient to produce rays of great penetrative power, such as will give a clear picture of a deeply seated bone, *e.g.* the hip, in three or four minutes. Dr. Leonard Hirshberg proves by a number of experiments that the species of anopheles mosquito (*A. punctipennis*) so abundant in and about Baltimore does not transmit malaria. There are also other excellent articles, but of purely medical interest.

Messrs. Hepburn and Waterston, in the April issue of the *Journal of Anatomy and Physiology*, continue their account of the histology of the motor-cells and accessory nerve in the spinal nerve-column of the porpoise. Another article in the same *Journal* contains the report of the second of a series of lectures by Prof. A. Robinson on the early development of the ovum and the differentiation of the placenta in various mammalian groups.

In the April number of the *Zoologist* the editor, Mr. W. L. Distant, commences a series of articles on rivers as factors in the distribution of animals, dealing in this instance with their restrictive action. Many instances are noted where rivers form the boundary to the range of species or groups of mammals, a notable case being the limitation of the area of the viscacha by the Uruguay River, although the country to the north appears in every way as well suited to the habits of that rodent as are the pampas to the south.

Three papers on vertebrates constitute the chief contents of the instalment of the *Proceedings* of the Philadelphia

Academy last to hand. In one Mr. J. A. G. Rehn continues his survey of the American bats, dealing in this instance with the genus Dermonotus (Pteronotus), a close ally of Chilonycteris, which, as already noticed in NATURE, formed the subject of his preceding article. Of the other two papers—both by Mr. H. W. Fowler—one is devoted to the description of berycoid fishes, and the second to certain fresh-water fishes from various parts of the United States.

THE presidential address to the Indiana Academy for 1902, which is only just to hand, in the *Proceedings* of that body, is devoted to a survey of the rise and progress of science in Indiana, which date practically from the conclusion of the war of secession. Special attention is devoted to the benefits conferred by science on agriculture, and it is pointed out that, as the result of these investigations, farmers in Indiana will eventually grow only such crops as are best suited to local conditions, and therefore the most remunerative.

THE second part of the first volume of *Records* of the Albany Museum contains five notes by Dr. R. Broom on South African anomodont reptiles. In one of these he discusses the affinities of the pavement-toothed genus Endothiodon, which was placed by Mr. Lydekker among the dicynodonts, but transferred by Prof. Seeley to the theriodonts. The new evidence demonstrates that the endothiodonts are so closely related to the dicynodonts that it is doubtful whether there is any cranial difference between the two groups, except the presence or absence of the palatal teeth.

AN excellent specimen of modern American zoological work is presented in a long and copiously illustrated article on the "Phylogeny of Fusus and its Allies," by Mr. A. W. Grabau, published in vol. xiv. of the *Smithsonian Miscellaneaus Collections*. The shells of gastropods, when complete, are admirably adapted for phylogenetic study, since they display the whole growth—from the protoconch onwards—externally. The characters of the protoconch are found to be of prime importance in the group in question, although these must be correlated with the structure of the adult shell. One of the most important results of this line of investigation is the discovery that the genus Cyrtulus, represented by a single species from the Pacific, instead of being inseparable from the Eocene Clavilithes, forms a perfectly distinct type. The well known shells from the Barton Eocene commonly designated in geological works *Fusus longaevus* are shown to indicate at least three specific types of Clavilithes, one of which is regarded as new, under the title of *C. solanderi*.

THE periodic growth of scales as an index of age in the various members of the cod family forms the subject of a very important paper by Mr. J. S. Thomson in the first part of vol. vii. of the *Journal* of the Marine Biological Association. It has long been known that such growths are annual in the carp, and it is therefore probable that the same holds good for salt-water fishes. So far as can be determined by observation and experiment, this induction appears to be well founded in the case of the Gadidæ, and the author is of opinion that, after making all due allowance for individual variation, the age of these fishes can be determined by the number of rings (not the smaller lines) in their scales. Labelling of individual fishes returned to the sea, after their scales have been examined, would afford definite proof of the truth (or otherwise) of the theory. The paper is illustrated with a number of excellent plates.

THE March number of the *Quarterly Journal of Microscopical Science* contains an important paper on the dermal fin-rays (dermotrichia) of fishes, by Mr. E. S. Goodrich, of the Oxford Museum. Such structures may be divided into three types. In the sharks and chimæras these rays (ceratotrichia) are unjointed and composed of a fibrous horn-like substance devoid of bone-cells, and unconnected with the placoid scales found in the skin. In Teleostomi (bony fishes and ganoids), on the other hand, we find small unjointed, horny rays (actinotrichia) on the edges of the fins, which are probably remnants of the ceratotrichia, and, in addition, branched, bony lepidotrichia, developed externally to the actinotrichia, and in primitive forms closely resembling the body-scales. They are probably derivatives from scales which once clothed the fins. Finally, the lung-fishes have jointed, bony rays (camptotrichia) containing bone-cells, and probably representing the lepidotrichia of the teleostomes. In the same issue the editor, Prof. E. Ray Lankester, re-publishes his "Encyclopædia" article on the Arthropoda, one reason for this being that it may readily come under the notice of foreign naturalists. Our readers may be reminded that the author considers the one great feature uniting chætopods, rotifers, and arthropods in a common group is the presence in each body-ring of a pair of hollow appendages—paropodia—moved by intrinsic muscles and penetrated by blood spaces.

ATTENTION was directed in NATURE (May 17, 1900) to an article by Mr. Lester F. Ward on the "Petrified Forest" of Arizona, and reference was then made to the presence of a petrified trunk which formed a "natural bridge" across a canyon. We have now received an article by Prof. Oscar C. S. Carter on "The Petrified Forests and Painted Desert

FIG. 1.—Agate bridge formed of petrified tree trunk, 111 feet long, spanning ravine in Arizona.

of Arizona" (*Journ.* Franklin Inst., April), and this contains a number of illustrations of the scenery, including the natural (agate) bridge, which we are enabled to reproduce. The silicified trunks of trees are considered to be of Triassic age, and most of them are relics of the denudation of the strata; that represented in the natural bridge is, however, *in situ*. The "Painted Desert" is so named on account of the bright colours of the sandstones, shales, and clays—the rocks being eroded into fantastic shapes, and being coloured blue, yellow, red or green in places; hence the effect in sunlight is brilliant. An illustration is given of pictographs made by cliff dwellers on a face of sandstone near the petrified forest. The silicified tree trunks mostly belong to forms allied to the Norfolk Island pine (Araucaria); other masses resemble red cedar. There are indications that the wood had commenced to decay before it was silicified. Prof. Carter believes that the petrifaction took place in the sandstone and shale, and was due to

soluble silicates derived from decomposition of the felspathic cement in the sandstone.

THE delegates of the Clarendon Press have in preparation, and will shortly publish, an authorised translation of "Das Antlitz der Erde," by Prof. Eduard Suess. This English edition of a standard work will be prepared by Dr. Hertha Sollas under the supervision of Prof. W. J. Sollas, F.R.S., and will contain a preface written for it by Prof. Suess.

THE *Electrician* Printing and Publishing Co. announce the early publication of a work by Mr. F. Soddy entitled "Radio-activity: an Elementary Treatise from the Standpoint of the Disintegration Theory." The same company will issue in a few days a book by Prof. S. Lemström, entitled "Electricity Applied to Agriculture and Horticulture."

A NEW edition of an illustrated price list of chemical apparatus has been published by Messrs. Brewster, Smith and Co., of Cross Street, Finsbury Pavement, E.C. The new catalogue contains above four hundred more illustrations than the previous issue, and also full particulars of several new devices of which we have already given descriptions.

THE eighth volume of the new half-yearly series of the *Transactions* of the Leicester Literary and Philosophical Society has reached us. It is edited by Mr. O. T. Elliot. The volume contains the presidential address of Dr. R. Pratt dealing with the subject of "over-strain" and "nervous-breakdowns," which are traced to a wrong use of leisure; four papers read before the society; and the quarterly reports of six of the sections into which the association is divided. We notice that this Leicester society was founded in 1835, and has thus had nearly seventy years of useful work.

ON account of the ease with which gold can be obtained in the pure state, the exact determination of its melting point is an important datum for high temperature measurements. Previous observers have given values ranging from 1061° (Callendar, Heycock and Neville) to 1091° (Barus), the average of the more recent work being 1064° C. In the current number of the *Comptes rendus* a new determination of this constant is described by MM. A. Jacquerod and F. L. Perrot, in which direct comparison with the gas thermometer, with fused silica bulb, is adopted. The heating was carried out in an electrical resistance furnace of special type, giving a complete control over the temperature in the neighbourhood of 1000° C. Owing to the smallness of the coefficient of expansion of silica, the correction for the expansion of the bulb amounts to only 2°, as against 35° to 40° for the same instrument with a platinum bulb. The mean result with the nitrogen thermometer was 1067°.2 C., and the results obtained when the bulb was filled with other gases showed that the coefficients of expansion of oxygen and carbon monoxide are very close to that of nitrogen.

THE additions to the Zoological Society's Gardens during the past week include a Lesser White-nosed Monkey (*Cercopithecus petaurista*) from West Africa, presented by Mr. T. P. Eykyn; two Mountain Ka-Kas (*Nestor notabilis*) from New Zealand, presented by Mr. T. E. Doune; a White-tailed Ichneumon (*Herpestes albicauda*) from Africa, six White-crowned Pigeons (*Columba leucocephala*) from the West Indies, two Large-billed Weaver-birds (*Ploceus megarhynchus*) from India, deposited.

OUR ASTRONOMICAL COLUMN.

COMET 1904 *a*.—Herr M. Ebell has calculated a new set of elements and an ephemeris for Brooks's comet, the former differing slightly from that published by Prof. Pickering. They have been derived from observations made on April 17, 20 and 24, and are given below:—

$$T = 1904 \text{ February } 28{\cdot}8792$$
$$\omega = 50^\circ\ 53'{\cdot}2$$
$$\Omega = 275\ 18{\cdot}5$$
$$i = 125\ 0{\cdot}0$$
$$\log q = 0{\cdot}42950$$

Ephemeris 0h. M.T. Berlin.

1904	α (h. m. s.)	δ (° ′)	log Δ	Brightness
May 2 ...	16 6 56	+52 44·4	0·3556	0·95
6 ...	15 50 5	+54 23·1		
10 ...	15 32 16	+55 44·8	0·3672	0·88
14 ...	15 13 50	+56 47·2		
18 ...	14 55 15	+57 31·9	0·3831	0·81

(Kiel Centralstelle *Circular*, No. 66).

It will be seen from the above ephemeris that the comet is travelling along just inside the southern border of Draco towards Ursa Major, and is becoming fainter. On May 6 it will be very near to, and south of, a small triangle of stars which is situated about 4° south of θ Draconis.

DIMINUTION OF THE INTENSITY OF THE SOLAR RADIATION.—In a communication to the Paris Academy of Sciences M. Ladislas Gorczyński publishes two tables showing, in the first, the mean monthly values of the solar intensity and the absolute humidity, and in the second the maximum values of these two quantities for each month during the years 1901, 1902 and 1903. The tables give the differences between the values for the corresponding month of each year, and show that the diminution in the intensity, which M. Dufour stated (*Comptes rendus*, vol. cxxxvi. p. 713) commenced in December, 1902, really commenced at Warsaw in May of that year. Until more positive evidence as to the effect of the dust ejected from Mont Pelée on the observed solar intensity is forthcoming, M. Gorczyński hesitates to ascribe the diminution to this cause (*Comptes rendus*, No. 5).

THE PERIODICAL APPARITION OF THE MARTIAN CANALS.—In a paper read before the American Philosophical Society Mr. Percival Lowell discusses the 375 drawings of the Martian surface made by him during the opposition of 1903. Having plotted the values allotted to the "visibility" of eighty-five canals, at different periods, with regard to the time of their minima visibilities after the Martian summer solstice, he found that these minima appeared in regular sequence from the North Pole towards the equator. Mr. Lowell believes that the canals are strips of vegetation dependent for their growth—and therefore for their visibility—upon the simultaneous presence of sunlight and water, and he points out that on a planet, such as the earth, where water is constantly present all over the surface, the appearance of vegetation solely depends upon the amount of sunlight received; therefore in the northern hemisphere it simply progresses northward with the sun. On the other hand, he concludes, from his curves, that there is no constant supply of moisture on the surface of Mars, and, therefore, although the sun may have reached the summer solstice, it is not until the snowcap melts and looses the water supply that the vegetation appears. Further, his curves indicate that when loosed the water moves southward at a remarkably steady rate of 53 miles per day, and, as the figure of the planet is shown by its spheroidity to be in a state of fluid equilibrium, he contends that the water must of necessity be conveyed southwards by artificial means.

The curves discussed are reproduced on seventeen plates which accompany the paper in No. 174, vol. xlii., of the *Proceedings* of the society.

ELEMENTS AND COMPOUNDS.[1]

I HAVE the honour of speaking to an audience of many men whom I have long venerated as my intellectual, although not my personal, teachers, and whom I admire as leaders in our common work for science. But however admirable the *present*, I am still more impressed by the thought of the *past* associated with this place. When, not long ago, I was engaged in electrochemical investigations and almost daily sought for information and enlightenment in Faraday's researches, I did not dare to think in my boldest dreams that one day I should find myself standing on the very spot in which he was wont to give the first accounts of the innumerable results of his indefatigable labours, his indomitable zeal, and his inexorable love of truth.

All that the pupil can do in such a case is to imbue himself as completely as he can with the ideas of the master and to try to perform his modest work in the master's spirit. But here arises a new difficulty: what subject ought I to choose? When I look into my own humble efforts, I find everywhere traces of Faraday. So far as relates to electrochemistry, the thing is plain; I think there is no word that I have oftener spoken or written than the word "ion," that word which was uttered for the first time in its modern sense in this very spot. But in other fields in which I have also worked, I feel the influence of his skilful hands and his keen vision. Catalysis, which I have studied during the past ten years, likewise came under his hands; and in the parts of the subject he worked at, the charm of secrecy and inexplicableness has been exchanged for the better qualities of a problem capable of resolution by earnest workers. And in one subject which has engrossed a very great part of my scientific activity, in the question of energy, I find the venerated master again a leader. He was indeed the first scientific man to direct all his investigations in view of the idea of the conservation and the mutual transformation of the various forces, as he called them, or the various kinds of energy, as we call them now.

This is a side of Faraday's mind to which, perhaps, not so much attention has been paid as it deserves. Although doubtless the greatest advance—the discovery of the quantitative proportionality between the energy which disappears and that which originates—was due to Mayer and Joule at a later date, yet the practical perception of this relation was working in Faraday's mind long before. There is indeed a great difference between the intellectual development of a scientific truth to a degree sufficient for the discoverer's *own* work, and to the degree required for its successful transfer to the minds of *other* workers. Faraday contented himself in this case, as well as in others (for example, in his conception of lines of force), with the first step. But that he had reached this step and stood firmly on it, that he used this conception constantly and regularly in his work, is evident from his constant reference to it from the first year of his scientific work onwards. From a closer study of his lectures and papers we learn that in every case he put the question: how can I change a given force into another? This continued to the very end of his work; for the last experiments he made related to the direct conversion of gravity into electricity, and although he did not succeed in his attempt, he was nevertheless convinced of the possibility of the conversion.

Guided by these considerations, I directed my attention to the very earliest problems treated by the master. Even before Faraday held the chair of chemistry here in the Royal Institution, as a youth of twenty-five years of age he practised the art of a lecturer in a small club, the City Philosophical Society, and the first course which he delivered there was on chemistry. In the sixteenth lecture, after a description of the metals, he concluded with the following general remarks:—

"To decompose the metals, then, to reform them, to change them from one to another, and to realise the once absurd notion of transmutation, are the problems now given to the chemist for solution. Let none start at the difficult task and think the means far beyond him; everything may be gained by energy and perseverance." And after a description of how in the course of history the means necessary for the isolation of the metals from their combinations have grown ever more and more efficacious, he mentioned the recent great discoveries of his master Davy as follows:—

"Lastly, glance but at the new, the extraordinary powers which the chemist of our own nation put in action so successfully for the reduction of the alkalies and the earths, and you will no longer doubt that powers still more progressive and advanced may exist and put at some favourable moment the bases of the metals in our hands."

When I try to follow this hint and take for the object of our consideration the question of the nature of the elements and of their compounds, I am aware that I am not the first who has done so in this place. If I am not mistaken, the very first chemist who had the honour of addressing you as a Faraday lecturer, Jean-Baptiste Dumas, lectured thirty-five years ago on the same subject. Nevertheless, I do not shrink from the repetition. Every generation of chemists must form its own views regarding this fundamental problem of our science. The progress of science shows itself in the way in which this is done. Faraday was at this time fully influenced by Humphry Davy's brilliant discoveries, and sought for the solution of the problem in Davy's way. For Dumas, the most important achievement of the science of his day was the systematising of organic chemistry, condensed into the concept of *homologous series*. He therefore regarded the elements as comparable with the hydrocarbon radicles, and tried to arrange them in similar series with constant differences in the numerical values of their atomic weights. It is well known that these ideas finally developed into the great generalisation we owe to Newlands, Lothar Meyer, and Mendeléeff. Although the problem of the decomposition of the elements was not solved in this way, these ideas proved to be most efficient factors in the general development of science.

From what store of ideas will a modern chemist derive the new materials for a new answer to the old question? A physicist will have a ready answer: he will construct the elements in a *mechanical* way, or, if he is of the most modern type, he will use *electricity* as timber. The chemist will look on these structures with due respect indeed, but with some reserve. Long experience has convinced chemists (or at least some of them) that every hypothesis taken from another science ultimately proves insufficient. They are adapted to express certain sides of his, the chemist's, facts, but on other not less important sides they fail, and the end is inadequacy. Learning by this experience, he makes a rule to use only chemical material for this work, and according to this rule I propose to proceed.

Hence, like Dumas, I put the question: what are the most important achievements of the chemistry of our day? I do not hesitate to answer: *chemical dynamics* or the theory of the progress of chemical reactions and the theory of chemical equilibrium. What answer can chemical dynamics give to the old question about the nature of the chemical elements?

The answer to this question sounds most remarkable; and to impress you with the importance I ascribe to this investigation, I will mention the result at once: *It is possible, to deduce from the principles of chemical dynamics all the stoichiometrical laws; the law of constant proportions, the law of multiple proportions and the law of combining weights*. You all know that up to the present time it has only been possible to deduce these laws by help of the atomic hypothesis. Chemical dynamics has, therefore, made the atomic hypothesis unnecessary for this purpose, and has put the theory of the stoichiometrical laws on more secure ground than that furnished by a mere hypothesis.

I am quite aware that in making this assertion I am stepping on somewhat volcanic ground. I may be permitted to guess that among this audience there are only very few who would not at once answer, that they are quite satisfied with the atoms as they are, and that they do not in the least want to change them for any other conception. Moreover, I know that this very country is the birthplace of the atomic hypothesis in its modern form, and that only a short time ago the celebration of the centenary of the atomic hypothesis has reminded you of the enormous advance which science has made in this field during the last hundred years. Therefore I have to make a great claim on your scientific receptivity. But still I do not hesitate one moment to lay the results of my work before you. For I feel quite sure

[1] By Prof. W. Ostwald. Faraday Lecture delivered before the Fellows of the Chemical Society in the Theatre of the Royal Institution on April 19.

that I shall find this receptivity unrestricted; and, moreover, I shall reap another advantage. For I also feel assured that you will offer me the severest criticism which I shall be able to find anywhere. If my ideas should prove worthless, they will be put on the shelf here more quickly than anywhere else, before they can do harm. If, on the contrary, they should contain anything sound, they will be freed here in the most efficacious way from their inexact and inconsistent components, so as to take the shape fittest for lasting use in science. And now let us go into the matter.

The first concept we start from is *equilibrium*. In its original meaning, this word expresses the state of a balance when two loads are of the *same weight*. Later, the conception was transferred to forces of all kinds, and designates the state when the forces neutralise one another in such a way that *no motion* occurs. As the result of the so-called chemical forces does not show itself as a motion, the use of the word has to be extended still further to mean that *no variation* occurs in the properties of the system. In its most general sense, *equilibrium denotes a state independent of time.*

For the existence of such a state it is above all necessary that temperature and pressure shall remain constant; in consequence of this, volume and entropy remain constant too. Now it is a most general experimental law, that the possibility of such a state, independent of time, is dependent on the *homogeneity* of the system. In non-homogeneous bodies, as, for instance, in a solution of different concentration in different places, or in a gaseous mixture of different composition in different places, equilibrium cannot exist, and the system will change spontaneously into a homogeneous state. We can therefore limit our considerations to this state, and we shall consider only bodies or systems of bodies in equilibrium, and, consequently, homogeneous.

Perhaps the possibility of the existence of water in contact with water-vapour might be considered contradictory to this statement, because we have here two different states and no homogeneity. Here we meet with the new concept created by Willard Gibbs, namely, that of a *phase*.

Systems of this kind are formed of homogeneous bodies indeed, but of more than one. The water in our system is homogeneous in itself, and the vapour too, and equilibrium cannot exist until both are homogeneous. But there is a possibility that a finite number of different homogeneous bodies can exist together without disturbing one another. In such a system we must have the same temperature and the same pressure everywhere, but the specific volume and the specific entropy may change from one body to the other.

We call a *phase* every part of the system where these specific properties exhibit the same value. It is not necessary that a phase should be connected to one body only; it may be distributed over any number of parts. In this way the millions of globules of butter in milk form only *one* phase, and the watery solution of casein and milk-sugar forms a second phase: milk is a two-phase system.

Every system consisting of only one phase has two degrees of freedom. This law involves only the assumption that the sole forms of energy involved in the system are heat and volume-energy; we exclude from consideration any effects due to gravitation, electricity, surface-tension, &c. This law is connected with the famous phase rule of Willard Gibbs, but is not identical with it, for it contains no mention at all of the so-called components of the system. Indeed, the law is valid in the same way for any pure chemical element, for example, oxygen, or for any mixture, for example, a glass of whisky and water. If you allow to the latter only one phase, it is impossible to change it in more than two ways, namely, in pressure and temperature.

The existence of such a body in the shape of only one phase is generally limited. If the pressure be lowered at constant temperature, a liquid or a solid will change at last into a gas. Lowering of temperature will change a gas into a liquid and a liquid into a solid. For every one-phase system it is possible to determine a "sphere of existence." This sphere is not necessarily limited on all sides; for gases we do not expect a limit on the side of low pressures and high temperatures, nor for solids on the side of high pressures and low temperatures. But on certain sides every phase has its limits, and most of these limits are experimentally accessible.

What will happen if we exceed the limit of existence of a phase? The answer is most simple: *a new phase will be formed.* The spheres of existence of the different phases therefore limit one another, and the boundary-lines represent the interdependent values of temperature and pressure for the possibility of the co-existence of both phases.

By granting the co-existence of two phases we lose therefore one degree of freedom. At the same time a new variation has arisen from the ratio between the masses of the two phases. For we must not suppose that this ratio is without influence on the state; indeed we find here two radically different cases.

The most general case is, that during the transformation of one phase into another the properties of both are continually changing, and the state of every phase is therefore dependent on the ratio of the two masses. By evaporating sea-water at constant temperature the density of the residue grows continually higher, while the pressure, and therefore the density, of the vapour goes on decreasing. If, however, we evaporate distilled water, we do not find any change in

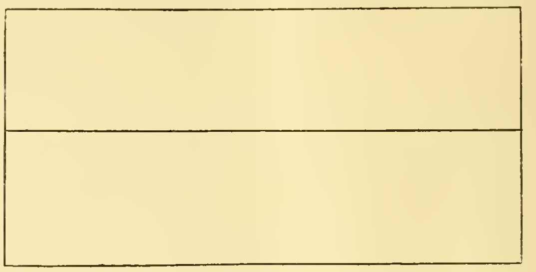

FIG. 1.

the properties of the residue and of the vapour during the whole transmutation.

Bodies of the first description we will call *solutions*, and of the second, *hylotropic bodies*. You will be inclined to call the latter substances or chemical individuals, and indeed both concepts are most nearly related. However, the concept of a hylotropic body is somewhat broader than that of a substance. But the possibility of being changed from one phase into another without variation of the properties of the residue and of the new phase is indeed the most characteristic property of a substance or chemical individual, and all our methods of testing the purity of a substance or of preparing a pure one can be reduced to this one property; anyone may readily convince himself of this by investigating any such method in the light of this description.

If we represent these cases by means of rectangular coordinates, taking as abscissæ the part of the first phase converted into the second, and as ordinates pressure or temperature, we get Fig. 1 for hylotropic bodies; they are represented by a horizontal straight line. With a solution we get a continuous line too, but not horizontal and generally not straight. If the ordinates are pressures at constant temperature, and the change is from liquid into vapour, the line will slope downwards as Fig. 2 shows. At other temperatures the lines will be of similar shape, only lying higher at higher temperatures and *vice versâ*. With other changes we obtain similar lines, sloping upwards or downwards as the case may be. For simplicity's sake we will consider in the future only vaporisation; this case gives the greatest possible variety, and we are sure not to omit anything by such a limitation.

What is the general process of change in a solution while it is being vaporised? The answer is quite distinct: *the residue is always less volatile* than the original solution, and *the distillate more volatile.* If there were an example of a solution behaving in the contrary way, then the process of vaporisation at constant temperature would be an explosive one. For the vapour begins to form at a given pressure; if by this the vapour-pressure of the residue were lowered, the vaporisation would continue of itself at a continually accelerated rate until all the liquid would be vaporised at once. It would be, in other words, a *labile* equilibrium. These equilibria are, however, only mathematical fictions, and have no experimental existence. If, on the contrary, the residue has a lower vapour-pressure, then the process is self-limiting, and shows the characteristics of a *stable* equilibrium. With hylotropic bodies we have an *indifferent* equilibrium, because the state is independent of the progress of the transmutation.

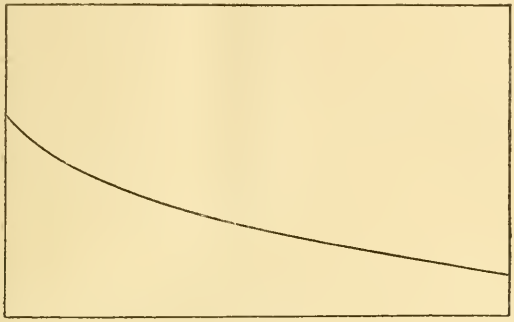

FIG. 2.

This being granted, we can ask: if we continue the separation of a solution into a less and a more volatile part by repeated distillation, what will finally become of it? Generally considered, two cases may happen. First the residue may become less and less, and the distillate more and more volatile, and there is no end to the progress. This case we may exclude from experimental evidence of a most general character, for we may take it as a general law that it is impossible to enhance any property beyond all limits, even by the unlimited application of our methods. We must conclude, therefore, that we shall ultimately meet with a *limit of volatility on both sides*, that finally we shall have separated our solution into a least and a most volatile part, and that both parts will not change further by repeated distillation. This is a most interesting result, for it means that *every solution can be resolved into components, which are hylotropic bodies.* For simplicity's sake we have considered only the case that two hylotropic components are generated by the process of separation; generally more than two may be formed, but in every case only a limited number of such components is possible. We may formulate therefore as a general law:—

It is possible in every case, to separate solutions into a finite number of hylotropic bodies.

From the components, we can compose the solution again with its former properties. This is also a general experimental law; if exceptions seem to exist, it is only because the case is not one of true equilibrium. Still we may limit our consideration to those cases where the law holds good. Then we have a relation between the properties of any solution, and the nature and relative quantity of its hylotropic components, which admits of only one interpretation. Every solution of distinct properties has also a distinct composition and *vice versâ*.

If we consider for simplicity's sake solutions of only *two* components, we may represent any property as depending upon the composition in a rectangular coordinate system, the abscissæ giving the composition and the ordinates the value of the property considered. In this way, we get a continuous line of a shape dependent on the particular case chosen.

If we consider the boiling points of all solutions formed by two hylotropic components, the most simple forms of curves (indeed the only experimental ones known) are given by the types I, II, and III, Fig. 3. For any solution, for example, the solution with the abscissa a, we can foretell its variation on distillation by the slope of the curve. For, as the residue must be less volatile, the residue will change to the ascending side of the curve. This is for I and III to the right, for II to the left side of the diagram. The change of the *distillate* is the opposite.

If we try to apply this criterion to the points m of the curve II and III, where there is a maximum and a minimum of the boiling point, we arrive at no decisive answer, for if the boiling point is already the highest possible it cannot rise, and if it is the lowest possible it cannot fall. We are forced therefore to conclude that the boiling point cannot change at all, that is, that this special solution must behave as a hylotropic body.

This is a well known theorem of Gibbs and Konovaloff, to wit, that a maximum or a minimum, generally spoken of as a *distinguishing point* in the boiling-curve, is necessarily connected with the property of distilling without change in the composition of the solution. A similar law holds good for the transitions from liquid to solid and from solid to gas.

Now this looks like a contradiction; while a few minutes ago we placed solutions in a class exclusive of hylotropic bodies, we have here solutions, that is, mixtures, which behave like hylotropic substances. But the contradiction vanishes if we consider a series of boiling-point curves corresponding to various pressures. We then find that the composition at the distinguishing point does not remain constant under different pressures, but shifts to one side, with alteration of pressure. This fundamental fact was discovered and experimentally developed in an admirable way by Sir Henry Roscoe, and has since proved itself a most important criterion in recognising a chemical individual.

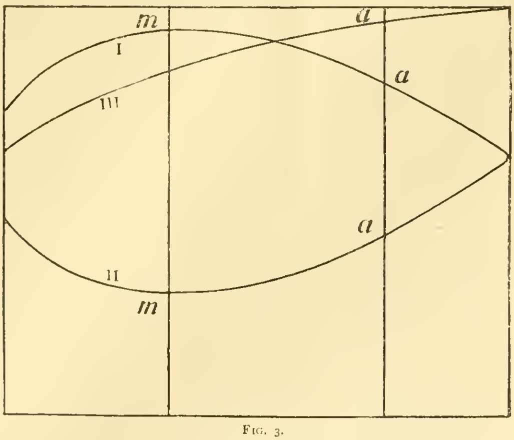

FIG. 3.

By drawing curves corresponding to various pressures, we get therefore generally the diagram shown in Fig. 4, the loci of the distinguishing points forming one curve. Between

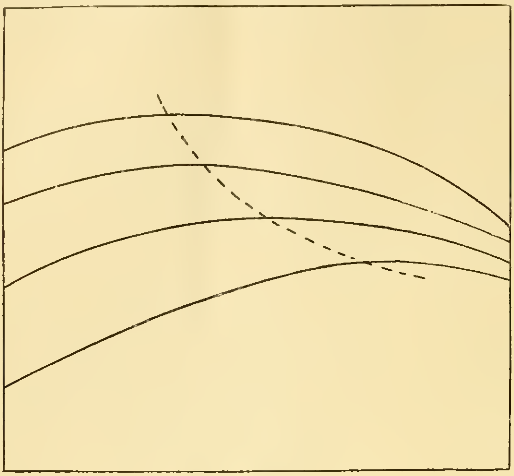

FIG. 4.

the infinite possibilities of the shape of this curve we have a distinguishing case again, the case that the curve is a *vertical straight line.* This means that the composition is independent of the pressure. *When this is the case, we call this hylotropic body a substance or a chemical individual.*

Therefore we conclude that a connection exists between solutions and chemical compounds or substances, the latter being a distinguishing case of the former. On the other hand, we get an exact definition: *a substance or a chemical individual is a body, which can form hylotropic phases within a finite range of temperature and pressure.*

Such substances can often be produced from other substances in the same way as a solution is, namely, by putting them together. If that can be done, we may infer from our definition that there exists a definite ratio between the components, independent of temperature and pressure between certain limits.

Now, *this is essentially the law of definite proportions*, the first of the stoichiometrical laws. We have deduced, therefore, the law of constant proportions from the concept of the chemical individual.

As you have seen, this deduction is extremely simple; the constancy of composition is a natural consequence of the mode of preparation and purification of chemical substances.

If we exceed the limits of temperature and pressure, where the body behaves as a hylotropic one, it assumes the properties of a solution, that is, its distinguishing point begins shifting in composition when the temperature is changed. Then it becomes possible to separate the body into its components, and we call this state the state of dissociation of the substance in question. In our graphic representation, the hitherto straight vertical line of distinguishing points turns sideways, Fig. 5. Most substances behave in this way, but there are substances which have never been transformed into solutions or the sphere of existence of which covers all accessible states of temperature and pressure. Such substances we call elements. In other words, *elements are substances which never form other than hylotropic phases.*

From this we may conclude that every body is finally transformable into elements, and into only *one definite set of elements.* For the most general case is a solution. Every solution can be separated into a finite number of hylotropic components, and these again can generally be transferred into a state when they behave like solutions and can be separated further. Finally, the components remain hylotropic through the whole range of temperature and pressure, that is, they are elements.

From the fact that the relation between a compound substance and its elements admits of only one qualitative and quantitative interpretation, we derive the conclusion that the resolution of any substance into its elements must always lead to the same elements in the same proportion. Here we find the source of the law of the *conservation of the elements.* This law is not generally expressed as a special stoichiometrical law, because we tacitly infer it from the atomic hypothesis. But it is truly an empirical law, and we see that it is not only a consequence of the atomic hypothesis, but also a consequence of the experimental definition of an element and of our methods of obtaining elements.

Here I should like to pause for a moment for the purpose of quoting a couple of historical facts. Up to the present moment, the question whether it is possible to deduce the stoichiometrical laws without the help of the atomic hypothesis has only been raised by other investigators in order to deny the possibility. So far as I am aware, there exists only one man who has worked upon the question with the earnest hope of obtaining an affirmative answer. Very few

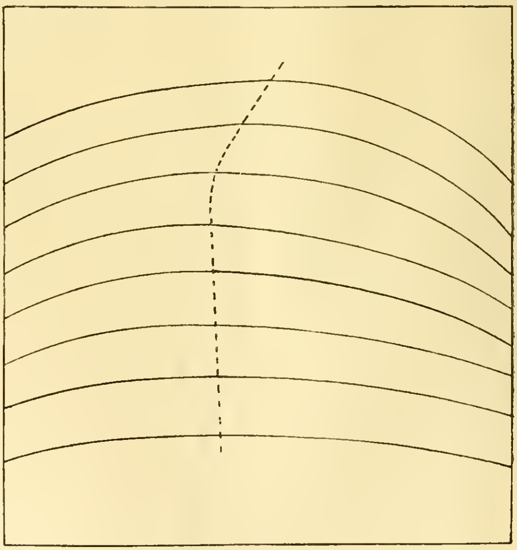

FIG. 5.

know his name. The man is Franz Wald; he is chief chemist at the iron works in Kladno, Bohemia. His papers on the subject are to be found in the *Zeitschrift*

für physikalische Chemie and in the *Annalen der Naturphilosophie*.

In the foregoing considerations, Franz Wald has played a great part. To him I owe first the idea that the definition of substances and elements is in a certain sense arbitrary, though very helpful and convenient. This definition is a condensed expression of our methods of separating and purifying these bodies. While, generally speaking, every solution has the same claim to be investigated as these bodies, the latter soon distinguish themselves as standards to which all other cases may be referred. To Franz Wald I owe further the idea that the conception of a *phase* is a far more general one than that of a substance, and that the deduction of the idea of a substance, and, further, the deduction of the laws governing the nature of substances, must start from the conception of the phase. I do not know whether Wald will agree with the way I have manipulated his ideas, but I feel it imperatively necessary to express my deep respect for, and my thankful obligation to, this solitary philosopher, who has prosecuted his work during a long series of years almost wholly without encouragement or sympathy from others.

Now there are still two stoichiometrical laws to be deduced, namely, the law of multiple proportions and the law of combining weights. I prefer to invert the order, and first to deduce the second law. It expresses the fact that it is possible to ascribe to each element a certain relative weight in such a way that every combination between the elements can be expressed by these weights or their multiples.

We suppose three elements, A, B, and C, given, which may form binary combinations, AB, BC, and AC, and besides these a ternary combination, ABC; there shall be but one combination of every kind. Now we begin by forming the combination AB; for this purpose, we must take a certain invariable ratio between the weights of A and B, according to the already proved law of constant proportions. Now we combine AB with C and get the ternary compound, ABC. There will be a certain ratio, too, between AB and C, and we can, if we put A as unity, assign to B and C certain numbers describing their combining weights relatively to A.

Now we begin to combine A with C forming AC, and then we form the ternary combination, ACB from AC and B. According to our law of a relation between elements and compounds, which can be interpreted only in one way, ACB cannot be different from ABC, and, in particular, it must show the same ratio between the relative weights of its elements. Therefore, the ratio of the weights of A and C in forming the combination AC cannot be other than that expressed by the relative combining weights already found in the first way. In other words, it is possible to compute the composition of the hitherto unknown combination AC, from analyses of the combinations AB and ABC. In the same way, we can compute the composition of the unknown combination BC, by help of the numbers obtained by the analyses of two other combinations of the same elements. To resume: the combining weights relatively to A regulate all other possible compounds between the elements concerned. But this is nothing else than the general stoichiometrical law of combining weights, for we can extend our considerations without difficulty to any number of elements.

Lastly, it is easy to deduce the law of multiple proportions from the law of combining weights. If no compounds can be formed except according to their combining weights, then, if there are two different compounds between A and B, we can form the one containing more of B either directly from A and B, or indirectly, combining first A and B to form the lower compound and then combining this with more of B. In applying the law of combining weights, we conceive that the weight of B in the higher compound must be twice its weight in the lower. The same consideration may be repeated, and finally we get the result, that instead of double the combining weight, *any multiple* of it may occur in combinations, but no other ratio.

If we cast a backward glance on the mental operations we have performed in the last two deductions, we recognise the method, the application of which has made the two laws of energetics so fruitful. In the same manner as the difference between the whole and the available energy is independent of the nature of the path between the same limiting points, the product of the chemical action between a number of given elements is independent of the way in which they are combined. If we compare two different ways, we get an equation between the characteristics of the two ways, and this is equivalent to a new law. In our case, this new law is the law of combining weights.

I will put the same idea into somewhat different words. By stating the equation between any two ways, we can get any number of different equations, each representing a new way as an experimental fact. Now, in order that all these equations shall be consistent, there must be some general law regulating the characteristics of the equations. For the consistency of the several equations in the case under discussion, the existence of specific combining weights, independent of the several combinations, is the necessary condition.

This is the main point of the considerations I wish to lay before you this evening. There are some secondary questions as to isomerides or allotropic states of substances, and there are other similar questions, but it would lead us too far to consider them one by one. I have investigated them on the same basis, and I can assure you that I have nowhere found an insurmountable difficulty or an impassable contradiction. All these facts find their proper place in the frame of the same general ideas.

Let me still add some words about the *nature of the elements*, as considered from my point of view. I wish to lay great stress on the fact that here, too, I find myself on the same ground as that on which Faraday built his general concepts during his whole scientific career. There is only one difference, due to the development of science. Faraday ever held up the idea that we know matter only by its forces, and that if we take the forces away, there will remain no inert carrier, but really nothing at all. As Faraday still clung to the atomic hypothesis, he was forced to express this idea by the conception that the atoms are only mathematical points whence the forces emerge, or where the directions of the several forces intersect; here his view coincided with that of Boscovich.

In the language of modern science I express these ideas by stating: *what we call matter is only a complex of energies which we find together in the same place.* We are still perfectly free, if we like, to suppose either that the energy fills the space homogeneously, or in a periodic or grained way; the latter assumption would be a substitute for the atomic hypothesis. The decision between these possibilities is a purely experimental question. Evidently there exist a great number of facts—and I count the chemical facts among them—which can be completely described by a homogeneous or non-periodic distribution of energy in space. Whether there exist facts which cannot be described without the periodic assumption, I dare not decide for want of knowledge; only I am bound to say that I know of none.

Taking this general point of view, in what light do we regard the question of the elements? We will find the answer, if we remember that the only difference between elements and compounds consists in the supposed impossibility of proving the so-called elements to be compounds. We are therefore led to ask for the general energetic properties underlying the concept of a chemical individual, whether element or compound.

The answer is most simple. The reason why it is possible to isolate a substance from a solution is that the available energy of the substance *is a minimum*, compared with that of all adjacent bodies. I will not develop this thesis at length, for it is a well known theorem in energetics or thermodynamics. I will only recall the fact that a minimum of vapour pressure is always accompanied by a minimum of available energy; and we have already seen that a minimum of vapour pressure or a maximum of boiling point is the characteristic of a hylotropic body or chemical individual.

This granted, we proceed to the question regarding the differences between the several substances. Expressed in the most general way, we find these differences connected with differences in their *specific energy content*. Temperature and pressure are not specific, for we can change them at will. Specific volume and specific entropy, on the contrary, are not changeable at will; every substance has its own

values of these. We may take therefore these values as the characteristics of the different substances. How many of such characteristics exist I cannot tell. Only for simplicity's sake I will assume that two of them are sufficient. As I will take care not to deduce any conclusions from this number, we shall not be led into error by accepting it.

We place these two characteristics in a system of planar coordinates; then the several elements will be represented by single points in the plane. We lay the plane horizontally and raise from these points ordinates, representing the available energy of each element. Between the points of the elements in the plane are situated the points of all possible solutions, filling up the whole plane. Each of these solutions will also have its available energy, and all the corresponding points in space will form a continuous surface. The form of this surface can be described in a general way. For as each *element* has its point in a *relative minimum*, the surface as a whole will have a shape like the ceiling of a cavern full of hanging stalactites, the end of each stalactite representing an element.

How can we pass from one element to another? Evidently not otherwise than by going over the higher parts of the surface, or the passes separating each stalactite from its neighbours. This can only be done by accumulating an appropriate amount of available energy in the element to be changed. Now the concentration of energy is a task we cannot accomplish *ad libitum*, for the possibility very soon ends. Think, for example, of compressing a gas into a given space. Up to some ten thousand atmospheres the work of compression will go on smoothly, but after that every metal begins to flow like a liquid, and you cannot proceed further. With the concentration of electric or any other energy the task is similar, and so we come to the conclusion that the concentration of energy can be pushed to only a very limited extent. The application of this result to our question about elements is simple enough: we cannot get over the pass between two stalactites because we cannot attain the necessary concentration of energy.

From the history of science we learn that these considerations contain at least some truth, for the isolation of the elements has ever been dependent upon the power of concentrating energy available at that time. The most brilliant example is the application of the voltaic pile to the isolation of the alkali metals by Humphry Davy.

Still I must confess that these last considerations are in a very embryonic state, and I should not have brought them before you if an unexpected application had not lately made itself manifest. Some years ago I explained these views to my old friend Sir William Ramsay, when he asked me how the idea of elements fitted into my conceptions of energy. Then I forgot all about it until Sir William reminded me of it, saying that his perplexing discovery of the transmutation of radium into helium might conceivably find some explanation in this way. This I am convinced of, and the considerations may be pictured in the following manner.

In the corner of our cavern where the elements with the highest combining weight are assembled, the stalactites are very short; and at last they are not really stalactites, but rather regions of different slope in the sloping ceiling. Where the plane is nearly horizontal a drop of water furnishes a picture of the stability of the elements. While hanging at the end of a true stalactite, more or less work must be done to raise the drop over the pass until it flows down another stalactite. But in this corner it will flow of its own accord, and only delay for a short time on the nearly horizontal portions in the ceiling.

Such elements will have only a *temporary existence*. Now we are sure that for the transmutation of one element into another enormous amounts of energy would be required, for the concentrations of energy as yet available have proved themselves insufficient for this purpose. We may expect, therefore, that enormous amounts of energy will be liberated if such an unstable element changes into a stable one. This accounts for the extraordinary quantity of energy developed by radium during its existence. The fact that radium changes into helium, an element with an exceptionally long stalactite (for it is impossible to get even any combination of helium), makes us expect indeed such an unusually great development of energy as is found to occur.[1]

The heat from radium is surely only the last form of the energy developed in its transformation. There are a great many intermediate forms, termed rays or radiations, which have been studied by a band of eminent workers, whose ingenuity and ability have been displayed in the most brilliant way during these investigations. Perhaps I may venture the suggestion that first, other intermediate temporary elements are formed, and that the energy liberated at this transmutation appears first in the shape of *new*, still imperfectly known forms. It is most likely that such forms are originated during the decay of the enormously concentrated energy of radium; at the same time it is probable that we have not yet the means of fixing these forms and so preventing their changing into other more common forms. We should remember that, for example, the conservation of electric energy at a pressure of some thousand volts during some months or years is by no means an easy thing, and I have great doubt if it is possible at all.

But here I must conclude, for I have ventured to intrude on a field where I have not secured my own right of entry by personal work. I see among my audience men who are possessed of an incomparably more minute and comprehensive knowledge of these new realms of science than I. I must ask you, therefore, to take these suggestions in the same spirit as that in which Faraday took his own speculations. They are questions put to nature. If she says Yes, then we may follow the same path a little further. If she says No—well, then we must try another path.

[1] Compare Soddy, "The Wilde Lecture," *Mem.* and *Proc.* Manchester Lit. and Phil. Soc., 1904. I am very glad to find that I am in close agreement (except in so far as there is a difference in his accepting the atomistic, while I hold by the energetic point of view) with this most zealous and fortunate worker; indeed, the above statements were written and printed before I saw Mr. Soddy's lecture.

A SMITHSONIAN MAGAZINE OF SCIENCE.

TO provide a medium for the early publication of the results of researches conducted under the auspices of the Smithsonian Institution, and especially for the publication of reports of a preliminary nature, a quarterly issue of the *Smithsonian Miscellaneous Collections* has been commenced. This new periodical has the form of an attractive magazine, and contains papers on a variety of subjects of scientific interest, most of them beautifully illustrated.

The number opens with a description of seventy new Malayan mammals, by Mr. Gerrit S. Miller, jun., based on collections made and presented to the U.S. National Museum by Dr. W. L. Abbott. Mr. C. G. Abbot presents the results of recent studies of the solar constant of radiation, conducted at the Astrophysical Observatory of the Smithsonian Institution, under the direction of Dr. S. P. Langley. Another paper by Mr. Abbot describes the new cœlostat and horizontal telescope of the Astrophysical Observatory, in which are given the results obtained with a device designed by Dr. Langley for the purpose of "churning" a column of air traversed by a solar beam, with the view of reducing the "boiling" or confusion of all parts of the solar image due to variability of the strata of air traversed. Dr. F. W. True presents some photographic illustrations of living finback whales from Newfoundland, these being the first photographs of living whales in American waters that have thus far been published. Brief descriptions of a skeleton of Hesperornis, and a new Plesiosaur, by Mr. Frederic A. Lucas, are given with plates, and Mr. W. H. Holmes illustrates and compares the designs on some remarkable shell ornaments from Kentucky and Mexico.

A noteworthy specimen of a Glacial pothole in the National Museum is described by Mr. George P. Merrill, who explains the method by which the specimen was procured. Some notes on the herons of the district of Columbia, by Mr. Paul Bartsch, who made a systematic survey of two heron colonies and conducted experiments with the view of solving some of the problems of bird life, are of special interest. Dr. J. Walter Fewkes gives a preliminary report on an archæological trip to the West Indies

in 1903, describing particularly the remarkable objects of stone, bone, shell, wood, and pottery which he collected during the trip, and giving an insight into their various uses. Dr. C. M. Child, of Chicago University, describes the form-regulation in Cœlentera and Turbellaria, of which he made a special study during his occupancy of the Smithsonian table at the Naples Zoological Station, and Dr. Carl H. Eigenmann introduces some new genera of South American fresh-water fishes, and new names for some old genera. Of timely interest is the account of Korean headdresses in the U.S. National Museum by the late Mr. F. H. Jenings, in which are described and illustrated twenty-four varieties of Korean hats and other headgear, including headband buttons and hatpins for topknots.

A brief history of the Hodgkins Fund of the Smithsonian Institution, and of what has been accomplished with its income toward "the increase and diffusion of more exact knowledge in regard to the nature and properties of atmospheric air in connection with the welfare of man," bears the name of Helen Waldo Burnside, and is accompanied with an illustration of the beautiful Hodgkins medal. Mr. A. B. Baker gives an account of a notable success in the breeding of black bears, which is of special interest to those having charge of animal collections. In a contribution on Chinese medicine, Dr. James M. Flint briefly explains the origin of medicine and the theory of disease in the Celestial Empire. The last of the series of articles consists of notes on the rocks of Nugsuaks Peninsula and its environs, Greenland, by Mr. W. C. Phalen, the remaining pages of the magazine being occupied by brief descriptions of various activities of the institution and their results.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The following is a copy of the speech delivered on April 28 by the Public Orator, Dr. Sandys, in presenting Prof. Ostwald, of Leipzig, for the degree of Doctor in Science *honoris causa*.

Viri et rerum naturae in scientiis excolendis et scientiarum illarum in terminis propagandis prospere occupati, non unius tantum populi intra fines angustos cohibentur, sed orbis terrarum totius inter cives merito numerantur. Nuper apud Londinienses Faradaii nostri memoriam oratione luculenta prosecutus est vir scientiarum laude illustris, qui a Germanis olim oriundus, Germanorum ultra terminum orientalem Russorum in imperio natus et professoris officio functus, postea in ipsam Germaniam atque adeo ad universitatem insignem Lipsiensem vocatus, in scriptis suis omnibus Germanorum gravitatem cum Francogallorum stilo lucido consociavit. Idem ne Europae quidem terminis contentus est, auctumno proximo (nisi fallor), velut alter Mercurius, Atlantis nepos facundus, etiam aequor Atlanticum transiturus. Quanta diligentia, memoria quam tenaci, ingenio quam multiplici praeditus, scientiae chemicae et scientiae physicae confinia quam diu quam feliciter lustravit, a collegis magnis sine ulla invidia peregre laudatus, a discipulis plurimis in omni orbis terrarum regione dilectus. Quot opera, inter sese quam varia, scientiae suae explicandae destinavit; idem etiam aliorum labores in Actis a sese tam diu editis quam diligenter in unum collegit, collectos in ordinem quam perspicuum redegit. Nemo mirabitur Actorum illorum librum prope quinquagesimum viri tanti in honorem nuper esse dedicatum, qui abhinc annos fere quinquaginta natus, vitae suae iam per partem dimidiam doctoris nomine decoratus est. Virum talem ad litora nostra honoris causa nuper vocatum, etiam nostro doctoris titulo libenter ornamus.

A COMBINED examination of non-resident candidates for open scholarships, exhibitions, &c., will be held at Trinity College, Clare College, Trinity Hall, Peterhouse, and Sidney Sussex College, Cambridge, beginning on Tuesday, December 6. Candidates will be examined at each college at the same time and by the same papers. Forms of application for admission to the examination may be obtained from any of the Tutors of Trinity College, the Senior Tutor of Clare College, the Master of Trinity Hall, the Senior Tutor of Peterhouse, or the Master of Sidney Sussex College. Entries should be made not later than November 18. Papers will be set in classics, mathematics, natural sciences, moral sciences and history. In mathematics and science the range of subjects included in the examination will be as follows:—*Mathematics*.—Arithmetic, geometry, algebra, trigonometry, elementary statics and dynamics, conic sections treated both geometrically and analytically, and the elements of the differential calculus. *Natural Sciences*.—Physics, chemistry, zoology, botany, physiology, and geology. Candidates for an emolument at Clare College may also offer elementary biology as a subject. Of these subjects no candidate may offer more than three. In making awards, excellence in one subject or in two subjects will be taken especially into account. There will also be (1) a paper of general questions in natural sciences which must be taken by all candidates who offer natural sciences, and (2) an optional paper in mathematics suitable for candidates who offer physics as one of their subjects.

THE Education Bill for Scotland was read a second time in the House of Commons on Monday by a majority of fifty-seven.

A LIST of the courses of lectures proposed for the summer term in the various German-speaking universities and technical schools is given in the *Physikalische Zeitschrift* for April 15.

THE foundation-stone of an extension of the Durham College of Science, Newcastle-on-Tyne, was laid on Monday by Mr. T. G. Gibson. The cost of the new buildings has been provided by a fund of 50,000*l*., raised to commemorate the life of the first Lord Armstrong, whose name the college will henceforward bear.

A COURSE of ten advanced lectures on the "Tracts of the Brain," by Dr. W. Page May, was commenced yesterday at University College, and will be continued on Wednesdays at 5 p.m. The lectures are open without fee to all internal students of the university.

THE following appointments are announced:—Dr. Friedrich Engel, of Leipzig, professor of mathematics in Greifswald; Dr. J. Schubert, of Eberswald, professor of physics, meteorology and geodesy; Dr. K. Hopfgartner, of Innsbruck, professor of chemistry; Dr. K. Schaum, of Marburg, extraordinary professor of physical chemistry; Prof. Paul Behrend, of Hohenheim, professor of organic chemistry; Prof. Lorenz, of Göttingen, ordinary professor of mechanics; and Prof. Roessler, of Charlottenburg, professor of electrotechnics—the last three at the Danzig Technical School; Dr. A. Hagenbach, professor of physics at Aachen; Prof. Moersch, professor of engineering at Zurich; Dr. Wedekind, of Tubingen, and Dr. Otto Dimroth, extraordinary professors.

REPLYING to a question in the House of Commons on April 27, Mr. Brodrick said that papers would shortly be laid on the table relating to the subject of the further maintenance of Coopers Hill College, including the report of the committee which sat last year. In consequence of the strong recommendations of that committee and the evidence brought before them, that efficient candidates for the Public Works Department in India can be provided by other engineering colleges at a less cost to the candidates and to the Indian Government, it has been decided to close the college. No decision, however, has yet been arrived at as to the date of closing, and all possible consideration will be shown to those concerned.

IN his presidential address at the recent annual general meeting of the Institute of Chemistry, Mr. David Howard reviewed the work of the council of the institute during the past year. Among other matters of interest he referred to the work of a special committee appointed to consider the advisability of instituting examinations for technical chemists. Mr. Howard said the most common difficulty at present is how to bridge over the gap between the scientific training and the practical work of the technical chemist. "What the chemist has to learn is to think in tons, not in grams." A large number of well known manufacturers consulted by the committee, while agreeing as to the value of a sound training in chemistry and physics, were emphatic that they did not want chemists trained or examined in the special technology of particular industries. The scheme drawn up by the committee is, as far as

possible, based on the opinions of the manufacturers. As Mr. Howard said, it is gratifying to know that in this investigation the institute can rely on the cooperation of so many leaders of industry, among whom are ironmasters, alkali, acid and general chemical manufacturers, brewers, cement makers, and representatives of dyeing, calico printing, and other important industries. A technical chemist possessing all the qualifications suggested by the manufacturers would be at once a competent mechanical engineer, electrical engineer, architect and surveyor, accountant and book-keeper, draughtsman, patent agent, and lawyer, in addition to being a capable chemist, and he would possess also special personal qualities, including the power of organisation, tact and general business capacity. The committee is strongly inclined to think that it is possible so to direct the post-graduate studies of the young chemist that he may adapt himself to technical practice, and thus not only improve his own position, but be better qualified to bear his part in the prevailing struggle of industry.

The King on April 28 laid the first stone of the new buildings for the Royal College of Science, Ireland, which are situated at Leinster Lawn, Dublin. The ceremony was commenced by the reading of an address by Sir Horace Plunkett, vice-president of the Department of Agriculture and Technical Instruction for Ireland, reviewing the work of the department as a whole, and especially that part of it entrusted to the Royal College of Science for Ireland. Referring to the latter, the address comments on the assistance received by the department from local authorities in the work of developing a system of technical instruction throughout Ireland, and points out the national value of a complete system of education. The King, in reply to the address, expressed his pleasure at performing the ceremony, and continued :—" In these days scientific training is an indispensable condition of success in commercial and industrial life. To be thoroughly effective it requires all the help which research and modern appliances can give. You are therefore wise in providing the improved equipment and the widened opportunity for instruction which this college will henceforth supply. You have told me that the efforts of your department to extend scientific education among the people have been supported by popular sympathy, and by the cooperation of representative public bodies. I am glad to receive this assurance; for without such sympathy and cooperation any scheme of technical instruction, however well devised, must fail to come into close touch with the life of the people, and must fall short of complete success. I agree with you in thinking that a complete system of education is necessary for the full realisation of your aims; and my best wishes go with your efforts to improve the intellectual and material conditions of the country." During his Irish visit the King also took another opportunity of emphasising the value of education in assisting the development of a country. At Kilkenny, in reply to addresses from a number of bodies, including the Kilkenny Agricultural Society, His Majesty said :—" I notice with pleasure the earnest efforts which are now being made for the industrial development of Ireland, and especially for the promotion of the agricultural industry, in which I take great practical interest. Agricultural prosperity, in my judgment, depends largely upon improved educational methods, cooperation, and better facilities for distributing produce. I am glad to know that, along these lines, progress is now being made in Ireland."

SOCIETIES AND ACADEMIES.

London.

Linnean Society, April 21.—Prof. S. H. Vines, F.R.S., president, in the chair.—Mr. Clement **Reid** exhibited drawings by Mrs. Reid of fruits and seeds of British pre-Glacial, inter-Glacial, and Roman plants: 2nd series—Calyciflorae. The most interesting addition to the inter-Glacial flora is the south European *Cotoneaster Pyracantha*, which occurs abundantly on the Sussex coast in deposits which yield also *Acer monspessulanum*, *Najas minor*, and *N. graminea*. The pre-Glacial Calyciflorae include *Trapa natans*, but the rest of the species yet determined are still living in Britain; many, however, need further examination. The plants from Roman Silchester include the vine, bullace, damson, and coriander.—Dr. O. Stapf, on behalf of Mr. W. B. **Hemsley**, exhibited some specimens of *Primula vulgaris*, Huds., which displayed the phenomenon of phyllody of the calyx in an unusual degree.

Physical Society, April 22.—Dr. R. T. Glazebrook, F.R.S., president, in the chair.—Calculation of colours for colour sensitometers and the illumination of "three-colour" photographic transparencies by spectrum colours: Sir W. de W. **Abney**. In three-colour photography, photographs have to be taken through a red, a green, and a blue screen, the transparencies or prints from which are then viewed. The exact shades and hues of these screens depend on the light which is used for viewing the transparencies or on the colours employed in printing. The present paper confines itself to the former case.—Normal piling as connected with Osborne Reynolds's theory of the universe: Prof. J. D. **Everett**. The paper maintains that, in a struggle for existence between different kinds of closest piling, represented by separate clusters with room to change their arrangements, normal piling possesses great advantages, first, in its six sets of lines of spheres, which serve as battering rams, and secondly, in its four sets of tiers in closest array, which facilitate the coalescence of adjacent clusters.—Note on the diffraction theory of the microscope as applied to the case when the object is in motion: Dr. R. T. **Glazebrook**. According to the Abbe theory of microscopic vision, when a grating is placed on the stage of a microscope and illuminated by plane waves, diffraction images are formed in the focal plane of the object-glass and the images in the view-plane result from these, and this is undoubtedly true. It is proved in this paper that the image in the view-plane may change without an alteration in the *position* of the diffracted images.—An "automatic gas-pump" was exhibited by Mr. C. E. S. **Phillips**. The apparatus is constructed upon a plan which enables the pump, when once set in operation, to continue automatically and to produce as perfect a Torricellian vacuum as is possible.

Edinburgh.

Royal Society, March 21.—Prof. Flint in the chair.—Dr. J. Erskine **Murray** exhibited and explained a differentiating machine, by means of which the first derivative of a given curve could be traced mechanically. A rod A is pinned at one end to a rectangular frame so as to be capable of revolution in the plane of the frame. A second rod B is retained by guides on the frame so as to be capable of motion only in the direction of its length. A pin in B engages in a longitudinal slot in A, and thus the distance between B and the pin about which A revolves is constant. The displacement of B relatively to the frame is therefore proportional to the tangent of the angle of inclination of A. If the revolving rod A be guided by hand so as to be always tangential to the given curve, a curve the coordinates of which are proportional to the differentials of the original curve is traced out by any point on B. The frame supporting the rods is free to move in direction X at right angles to the rod B. In order to eliminate the y-coordinate of the original curve, the board on which the derived curve is traced is free to move in OY but not in OX.—Dr. J. **Halm** gave an account of his spectroscopic observations of the rotation of the sun, which had been carried on at the Royal Observatory, Edinburgh, since 1901. The method employed was essentially that used by Duner, but some simplification and greater steadiness of the apparatus had been secured by the employment of a siderostat and heliometer. The results so far obtained seem to point to a decisive influence of solar activity upon the surface rotation. By arranging the results in two groups, one comprising the observations of 1901–2, a time of sun-spot minimum, and the other those of 1903, at a period of vigorously renewed solar activity, Dr. Halm obtained undoubted evidence of the existence of systematic differences between these two groups of quite unexpected magnitude. The decrease of angular velocity from the equator towards the poles, as observed in 1901–2, agreed very well with that found by Duner in 1887–9, also at a time of sun-spot minimum. But the appearance of spots in 1903 was accompanied by an extraordinary increase of angular

velocity in high latitudes. It seemed as if the spots had caused the superficial layers to rotate more in accordance with the law of rotation of a rigid body, a mode of statement, however, which was not to be accepted as involving any physical theory.—In a paper on the viscosity of aqueous solutions of chlorides, bromides, and iodides, Dr. W. W. **Taylor** and Mr. Clerk **Ranken** gave determinations of the relative viscosities of KCl, KBr, KI, HCl, and HBr, in solutions containing 1 mol., 2 mol., and 3 mol. per litre at 0°, 15°, and 25°. The effect of temperature change and concentration on the viscosity was found to be different for the chlorine, bromine, and iodine solutions. The molecular conductivities of the fifteen solutions at 0° were also determined, and showed no greater differences than for solutions of similar concentration at 18°.—In a note on the unit of relative viscosity and on negative viscosity, Dr. W. W. **Taylor** pointed out the disadvantages of expressing the relative viscosities of solutions by taking as unit the viscosity of the solvent at the temperature of experiment. Instead, they should all be referred to water at 0° as standard. Until quite recently only aqueous electrolytes were known to exhibit the phenomenon of "negative viscosity," *i.e.* the viscosity of the solution less than that of the solvent at the same temperature. According as the temperature coefficient of the solution is greater or less than that of the solvent, a solution may exhibit negative viscosity at high temperatures or at low temperatures.—In a paper on the action of chloroform on the heart and arteries, Prof. **Schäfer** and Dr. **Scharlieb** showed, as had been previously proved by Gaskell, McWilliam, Hill, Embley, Sherrington, and others, that chloroform has a powerfully paralysing action upon the mammalian heart, inducing in it a condition in which all irritability is lost, and is only recoverable by washing away the poison by passing a stream of unpoisoned blood or saline solution through the cardiac vessels. They further show that this paralytic condition is not due to vagal inhibition, which is only rarely to be seen in chloroform anæsthesia, and is then probably due to dyspnœa; it is therefore not capable of being antagonised by atropine. Even such a powerful agent as suprarenal medulla, which is one of the strongest cardiac stimulants known, is powerless to provoke contraction in a heart paralysed by chloroform. But sometimes artificial respiration by chest compression may, by inducing some sort of circulation through the coronary vessels, cause the removal of the drug from the heart. No benefit has been obtained by directly "massaging" the heart. The addition of a small percentage of ammonia vapour to the chloroform-laden air used for inhalation is shown to have a markedly beneficial effect upon the result, the heart's force and the blood pressure and respiration being maintained far better than with chloroform alone. Alcohol vapour has a similar but less marked effect. On the other hand, too large a proportion of ammonia vapour is liable to produce instant and permanent arrest of the heart's action. While the respiration usually stops before the heart, in some cases the cessation is simultaneous, and in a few the heart ceases before the respiration. After having completely stopped the heart may after a minute or two recommence to beat, but the respirations rarely begin again spontaneously, except that, as in asphyxia, a staircase of about a dozen respirations may make its appearance long after the ordinary respiratory movements have ceased. These are, however, ineffectual to produce recovery, and if artificial respiration be not resorted to the heart soon ceases permanently. The effect of chloroform upon the arterioles has been determined both in the frog and in the isolated mammalian kidney by perfusion of Ringer's solution containing dissolved chloroform. In the frog, solutions containing from 1 in 200 to 1 in 20,000 produce constriction of arterioles in proportion to the amount of chloroform contained in solution. In the mammal, while stronger solutions (such as 1 in 500) produce powerful constriction of arterioles, dilatation is obtained with weaker solutions (1 in 5000), a strength which in the frog produces marked contraction. This confirms an observation by Dr. C. J. Martin, recently communicated to the Physiological Society. Further experiments are needed to clear up this discrepancy between the results in the frog and mammal.—Mr. G. A. **Carse** communicated a paper on the thermal expansion of solutions of the hydroxides of sodium, barium, and strontium, in each of which the volume of the solution is less than that of the water used in its preparation. In the case of sodium hydroxide the expansion in all cases, whether positive or negative, increased algebraically with rise of temperature. The same was true for strontium hydroxide. In the case of barium hydroxide the expansion was so small and the variation with temperature so slight that nothing definite could be predicated, although all solutions examined agreed in giving negative expansion. With sodium hydroxide the maximum contraction point slowly shifted towards the concentration origin with rise of temperature.—Mr. John **Dougall** presented a complete and elaborate discussion of the analytical theory of the equilibrium of an isotropic elastic plate. The solution was obtained in the first instance for an infinite plate, and was then applied to cases of finite plates.—The Rev. F. H. **Jackson** communicated a theorem relating to a generalisation of the Bessel function.

PARIS.

Academy of Sciences, April 25.—M. Mascart in the chair. Report presented by the commission charged with the scientific control of the geodesic operations at the equator. A description of the work done during the year 1903, and a sketch of that proposed for 1904 and 1905. Unfavourable meteorological conditions interfered considerably with the work done last year.—M. Bigourdan was elected a member in the section of astronomy in the place of the late M. Callandreau, and M. Gordan a correspondant for the section of geometry in the place of the late Prof. Salmon.—Note on an earthquake at Roustchouk, in Bulgaria, communicated by the French consul.—Observations on the comet 1904 *a* (Brooks), made at the Observatory of Besançon: P. **Chofardet.** On April 19 the comet appeared as a star of the ninth magnitude, with a rounded head 1′ in diameter, and with a central nucleus. There was a slight tail from 2′ to 3′ in length in the direction of the south-west.—Observations on the comet 1904 *a* (Brooks), made at the Observatory of Paris: M. **Salet.**—Provisional elements of the Brooks comet (1904, April 16): G. **Fayet.**—The Leonids in 1903, and the determination of their height by means of simultaneous observations: Maurice **Farman,** Em. **Touchet,** and H. **Chrétien.** The simultaneous observations were carried out at stations 28·7 kilometres apart, and results were obtained for eighty-three meteors. The average height of the first appearance was 103·6 kilometres (extremes 138·5 and 53·9), of disappearance 75·8 (extremes 131·6 and 33·4), the average length of the trajectory being 35·2 kilometres.—On the singularities of analytical functions: L. **Zoretti.**—An attempt at a determination of the difference of longitude chronometrically: Paul **Ditisheim.** The difference of longitude between Paris and Neuchâtel was determined by carrying with special precautions five chronometers between the two places, the mean result being 18m. 28·86s. It is proposed to check this by a new telegraphic determination.—On the fall of water in rivers: Edmond **Maillet.**—On the melting point of gold and the expansion of some gases between 0° and 1000° C.: Adrien **Jacquerod** and F. Louis **Perrot** (see p. 14).—On the atomic weights of hydrogen and oxygen, and on the probable value of their atomic ratio: Ph.-A. **Guye** and Ed. **Mallet.** The method proposed by Vallier for treating a limited number of observations is applied to the reduction of the observations of E. W. Morley on the atomic weights of hydrogen and oxygen. The final value is $O=15\cdot8787$ for $H=1$.—Experimental researches relating to some cyclic amines: P. **Lemoult.** The heats of combustion of some amines calculated by means of the formula given by the author in a previous paper show in a few cases wide deviations, and it appeared advisable to re-determine experimentally some of these measurements. The results of determinations made with the Berthelot bomb for xylidine, monoethylaniline, *p*-anisidine, α-naphthylamine, and β-naphthylamine are given, and agree with the figures calculated from the formula within 0·5 per cent.—The formation of hydrogen silicide by direct synthesis from its elements: A. **Dufour.** At a very high temperature, hydrogen and silicon unite directly to form hydrogen silicide. The amount formed is small, and the product was identified by its chemical re-

actions and its boiling point (−116° C.).—The lead-aluminium alloys: H. **Pécheux.** Alloys containing 93, 95 and 98 per cent. of aluminium were obtained, the properties of which are described.—On colloidal gold: M. **Hanriot.** Colloidal gold, prepared by the method of Henrich, exhibits properties which are inconsistent with the assumption that it consists merely of finely divided gold.—A new indicator and its application to the detection of boric acid: Lucien **Robin.** The indicator proposed is extracted from mimosa flowers by weak alcohol. Its general behaviour is similar to that of phenol-phthalein, with the advantage that it can be used in the presence of ammonia. It gives a characteristic reaction with borates, and may be used for this purpose in the analysis of food products.—The action of magnesium and organo-magnesium compounds on bromophenetol: V. **Grignard.** Bromophenetol reacts readily with magnesium powder, giving ethylene and $C_6H_5O:MgBr$ instead of the normal compound $C_6H_5OCH_2CH_2MgBr$.—On the lactone of oxy-crotonic acid and the γ-substituted crotonic acids: M. **Lespieau.**—Researches on the dinaphthopyranic series: R. **Fosse.**—Remarks on some peculiarities of the flora of Long Island: Ph. **Eberhardt.** The views of the author given in previous papers on the influence of the amount of atmospheric moisture on the growth and development of plants have received confirmation from a study of the growth of vegetation on Long Island.—Researches on the browning of the vine: L. **Ravaz.** The browning of the vine is a particular case of impoverishment of the plant brought about by production. It may be avoided by the use of manures rich in potash.—On the evolution of the relief of the plateau of Mehedinti, Roumania: E. **de Martonne.**—On the faults and undulations of the secondary and tertiary layers of the Loir: Jules **Welsch.**—On an albumen extracted from the eggs of fishes: the comparative chemistry of the sexual products in the same species: L. **Hugounenq.**—Autolysis of the tissues of the animal organism and the genesis of morbid phenomena: A. **Charrin.**—The colloidal state of metals in mineral waters; natural oxydases and their therapeutic action: F. **Garrigou.**—On a mechanical apparatus allowing of trepanning and vibratory massage: M. **Bercut.**

DIARY OF SOCIETIES.

THURSDAY, MAY 5.

ROYAL SOCIETY, at 4.—Election of Fellows.—At 4.30—Experiments on a Method of Preventing Death from Snake Bite, capable of Common and Easy Practical Application: Sir Lauder Brunton, F.R.S., Sir Joseph Fayrer, Bart., F.R.S., and Dr. L. Rogers.—A Research into the Heat Regulation of the Body by an Investigation of Death Temperatures: Dr. E. M. Corner and Dr. J. E. H. Sawyer.—(1) A Note on the Action of Radium on Micro-organisms; (2) Further Note on Some Additional Points in Connection with Chloroformed Calf Vaccine: Dr. A. B Green.—On Certain Physical and Chemical Properties of Solutions of Chloroform in Water, Saline, Serum and Hæmoglobin. A Contribution to the Chemistry of Anæsthesia—Preliminary Communication: Prof. B. Moore and Dr. H. E. Roaf.

LINNEAN SOCIETY, at 8.—British Freshwater Rhizopoda: J. Cash.—On Coloration in Animals and Birds: J. Lewis Bonhote.—On the Cranial Osteology of the Fishes of the Families Mormyridæ, Notopteridæ and Hyodontidæ: Dr. W. G. Ridewood.

RÖNTGEN SOCIETY, at 8.30.—The Röntgen Society; its Past Work and Future Prospects: J. J. Vezey.—Some Experiments with Alpha Rays: F. H. Glew.

CHEMICAL SOCIETY, at 8.—The Slow Combustion of Ethane: W. A. Bone and W. E. Stockings.—Note on the Hydrolysis of Starch by Diastase: J. S. Ford.—The Reesin Acids of the Coniferæ. Part I. The Constitution of Abietic Acid: T. H. Easterfield and G. Bagley.—The Action of Radium Rays on the Halides of the Alkali Metals, and Analogous Effects produced by Heat: W. Ackroyd.—The Dynamic Isomerism of Glucose and of Galactose. Solubility as a means of Determining the Proportions of Dynamic Isomerides in Equilibrium: T. M. Lowry.—A Study of the Substitution Products of *ar*-Tetrahydro-α-naphthylamine, *ar*-4-Bromotetrahydro-α-naphthylamine and *ar*-Tetrahydro-α-naphthylamine-4-sulphonic acid: G. T. Morgan, Miss F. M. G. Micklethwait, and H. B. Winfield.—The Additive Products of Benzylideneaniline with Methylacetoacetic Ester and Acetoacetic Ester: F. E. Francis and Miss M. Taylor.

INSTITUTION OF MINING AND METALLURGY, at 8.—Discussion on Laboratory Equipment (conclusion).

FRIDAY, MAY 6.

ROYAL INSTITUTION, at 9.—Anthropoid Apes: Dr. P. Chalmers Mitchell.

PHYSICAL SOCIETY, at 8.—An Experiment with Lubricating Oil: W. A. Price.—Some Instruments for the Measurement of Large and Small Alternating Currents: W. Duddell.—Exhibition of Apparatus from the National Physical Laboratories.

MONDAY, MAY 9.

ROYAL INSTITUTION, at 5.—General Monthly Meeting.

FARADAY SOCIETY, at 8.—Studies in Viscosity: Dr. C. E. Fawsitt.—The Electrolytic Oxidation of Anthracine: Alberto Fontana and F. Mollwo Perkin.

SOCIETY OF ARTS, at 4.30.—The Majolica and Glazed Earthenware of Tuscany: Prof. R Langton Douglas.

TUESDAY, MAY 10.

ROYAL INSTITUTION, at 5.—Meteorites: L. Fletcher, F.R.S.

SOCIETY OF ARTS, at 8.—Crystalline Glazes and their Application to the Decoration of Pottery: W. Burton.

WEDNESDAY, MAY 11.

SOCIETY OF ARTS, at 8.—Early Painting in Miniature: R. R. Holmes.

GEOLOGICAL SOCIETY, at 8.—On some Quartzite-Dykes in the Mountain Limestone near Snelston (Derbyshire): H. H. Arnold-Bemrose.—Phenomena bearing upon the Age of the Lake of Geneva: Dr. C. S. DuRiche Preller.

THURSDAY, MAY 12.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—If the discussion on Messrs. Merz and McLellan's paper is concluded at the meeting of May 5, Messrs. Parsons, Stoney and Martin's paper on the Steam Turbine as applied to Electrical Engineering will be read and discussed.

MATHEMATICAL SOCIETY, at 5.30.—Some Mathematical Instruments: C. Cooke (communicated by Major P. A. MacMahon).—On the Evaluation of Certain Definite Integrals by Means of Gamma Functions: A. L. Dixon.—Generalisations of Legendre's Formula

$$KE' - (K - E)K' = \tfrac{1}{2}\pi:$$

A. L. Dixon.—Note on the Integration of Linear Differential Equations: Dr. H. F. Baker.

SOCIETY OF ARTS, at 4.30.—British Grown Tea: A. G. Stanton.

FRIDAY, MAY 13.

ROYAL ASTRONOMICAL SOCIETY, at 5.

MALACOLOGICAL SOCIETY, at 8.—List of Mollusca collected during the Commission of H.M.S. *Waterwitch* in the China Seas, 1900–1903, with Descriptions of New Species: Surgeon K. Hurlstone Jones, R.N., and H. B. Preston.—On a Carboniferous Nautiloid from the Isle of Man: G. C. Crick.—Notes on the Genus Anoma: E. R. Sykes.—New Land Shells from New Zealand: Henry Suter.

SANITARY ENGINEERING.

Refuse Disposal and Power Production. By W. Francis Goodrich, A.M.Inst.M.E. Pp. xv+384. (Westminster: Constable and Co., Ltd., 1904.) Price 16*s*. net.

THE destruction of town refuse by fire is a comparatively modern development; the first furnaces erected for such a purpose were constructed to the designs of Mr. Fryer at Manchester in 1876, and these furnaces, though considerably modified, are still at work. The gross insanitary character of the ordinary system of refuse disposal is patent to everyone who has occasion to move about in the neighbourhood of any of our large cities; the refuse is deposited in tips; often an old quarry or gravel pit is selected for this purpose, and the refuse is dumped into these cavities until they are filled up. How unsatisfactory this is has been proved by the fact that outbreaks of disease have occurred directly traceable to the existence of these heaps of abomination. The author states that an outbreak at Fratton was certified by the medical authorities to be due to the contagion brought by flies bred in the pestiferous heaps of Portsmouth refuse which had been deposited in this neighbourhood. These refuse heaps in the summer time breed flies in millions, and they are the constant resort of rats, which spread from them all over the neighbourhood, and how readily most dangerous diseases are disseminated by both these agencies is well known to all medical authorities. We had this fact brought home to us clearly during the late campaign in South Africa, when the nurses and doctors in the field hospitals were frequently able to tell that a patient being brought in was a typhoid sufferer from the swarms of flies round him.

Fortunately the Local Government Board is setting its face steadily against a continuation of this insanitary practice, and the recent example at Bury St. Edmunds, quoted by Mr. Goodrich, where the board refused to sanction a loan for the purpose of purchasing land for a tip, is a striking illustration of this modern tendency. Refuse tipping at sea, owing to the fact that much of the refuse is liable to be washed back on the foreshore, and also that it has frequently to be stored for lengthy periods owing to stormy weather, is an equally unsatisfactory method.

The book is fully illustrated, and two or three of the illustrations, reproduced from photographs, show the filthy state of affairs brought about by town authorities neglecting to avail themselves of modern appliances. The author discusses very fully the various systems of burning refuse in destructors which have been adopted in this country, for it is chiefly in Great Britain that fire purification has been adopted, and the various systems of charging the refuse into the destructor cells are described in detail; the direct charging systems are compared very fairly with the hand or shovel feeding systems.

Though the former, from the sanitary point of view, naturally appears the more desirable, there can be little doubt from the figures given by Mr. Goodrich that there is not much economy in labour by the adoption of direct charging, since the labour of dragging the material from the drying hearth forward on to the grates is greatly increased. The first types, founded on a system of natural draught and low temperatures in the cells, undoubtedly did much to retard the development and the introduction of destructors, and in this connection to Mr. Charles Jones, of Ealing, must be given much credit, because his cremator certainly led the way to the design of the modern forced draught high temperature destructor.

Illustrations and descriptions are given of most of the destructors which have been used up to the present time, and then the author deals exhaustively with the labour cost in the different systems, with the utilisation of the clinker, and with the application of the steam generated to electricity works, sewage works, or waterworks. The figures given for the labour cost show very striking variations in the different towns, ranging from as low as $6\frac{3}{4}$*d.* per ton of refuse burnt to as high as 2*s.* 10*d.*; the higher cost in a few cases arises from the fact that the quantity of refuse to be destroyed is comparatively small, and therefore the three shift, eight hour system, which is the more economical, cannot be adopted.

The disposal of the clinker no longer presents any real difficulty, as in the modern destructor the temperature is easily kept high enough and sufficiently steady to produce a thoroughly hard, well burnt clinker suitable for many purposes. The late Mr. J. McTaggart, of Bradford, did much in directing attention to the various uses to which the clinker could be applied, and the results he obtained were remarkable; clinker bricks, clinker tiles, clinker mortar, clinker concrete were some of the products into which his waste material was converted, and Bradford led the way in showing that by the utilisation of this residuum, which amounts on an average to about one-third of the weight of the total refuse consumed, much of the cost of running a destructor can be repaid. The utilisation of the steam generated has also made great strides during the past few years, and at the present time there are, the author states, sixty combined electricity and destructor works either running or under construction in this country, several of them of considerable size, the electricity generated being used both for lighting and for traction.

The author gives a comparative statement showing the number of electrical units generated per ton of refuse destroyed in twenty of these stations, the figures ranging from as low as 15 to as high as 80 per ton of refuse burnt. He quotes, from reports of station engineers, opinions which show conclusively that whatever difficulties may have been experienced at first, owing to variations in the steam pressure, at the present time it is quite as easy to run a plant satisfactorily with steam produced from the waste heat of the destructor furnaces as when generated in an ordinary boiler using coal or other fuel. About thirty-eight towns are using steam from the destructors for driving pumping plants in connection with sewage dis-

posal works, and the town of Sheerness has taken a still bolder departure in the application of such steam to work pumps supplying the town with water. This latter scheme was carried out by the author himself, and he is thus able to give full details as to the economical results of this installation; the first six months' working showed a saving of nearly 500*l.*, equal to a reduction of 3*d.* per 1*l.* in the town rates. The comparative advantages of steam jet blowers and fans are contrasted, and Mr. Goodrich clearly leans towards the former as the more economical in the long run; in this connection he lays great stress upon the absolute necessity of systematic tests of the waste gases in order to determine whether or not combustion is going on under the most economical conditions; a diagram given on p. 157 shows how serious the heat losses may be if excess air is used.

The second half of the book is devoted to a description of all the refuse destructors which have been put to work in Great Britain and abroad up to the present time. The date of the installation, the type and make of destructor, the number of cells, the number and type of boilers, height of chimney, the type of draught used, the purpose for which the power is used, the weight of the refuse destroyed daily, and the labour cost per ton of refuse destroyed are all given. Most complete information in regard to this important subject has thus been brought together, and there can be no doubt that it will prove a most useful reference volume to those engaged in planning such plants, and to municipal authorities who are considering the desirability of erecting destructors. Up to the present the various details and results given by Mr. Goodrich have been scattered through the *Proceedings* of one or two of our engineering societies, or embodied in the reports of borough engineers, and it can have been no light task to gather together the mass of information in this book. We have no hesitation in saying that it will be a standard book of reference for several years to come, and it is in a form in which it will be comparatively easy, in the re-issue of fresh editions from time to time, to keep it up to date.

T. H. B.

GEMS AND PRECIOUS STONES.

Precious Stones, a Popular Account of their Characters, Occurrence and Applications, with an Introduction to their Determination, for Mineralogists, Lapidaries, Jewellers, &c., with an Appendix on Pearls and Coral. By Prof. Max Bauer. Translated from the German, with additions by L. J. Spencer. Pp. 627; with 20 plates and 94 figures in the text. (London: Charles Griffin and Co., Ltd., 1904.) Price 42*s.* net.

Gems and Gem Minerals. By Dr. Oliver Cummings Farrington. Pp. 229; with 16 coloured plates and 60 half-tone and line engravings. (Chicago: A. W. Mumford, 1903.)

THE publication in 1890 by the Scientific Publishing Company of New York of Dr. G. F. Kunz's valuable "Gems and Precious Stones of North America" showed for the first time the possibility of producing, by modern methods of photolithography, illustrations of gems, either cut or uncut, which would give some idea of their characteristic colour, transparency and lustre. The two works of which the titles appear above have adopted the same methods of illustration, and the plates are scarcely inferior in beauty and in fidelity to the originals to those which adorn Dr. Kunz's well known book.

Prof. Max Bauer's "Edelsteinkunde" was issued in parts in 1895 and 1896, and at once took a foremost place in scientific literature as the standard work on all subjects relating to gems. It deals not only with the methods adopted by mineralogists and others for determining the mineral species to which gem stones must be referred, but with such questions as their artificial production, counterfeiting of gems, and their alteration by heating, &c.—questions upon which it is often very difficult to obtain satisfactory and trustworthy information. While mainly devoted to gems viewed from the scientific standpoint, much valuable information is added on the cutting, mounting and price of gems, while the accounts of the localities and mode of their occurrence are exceptionally full and complete, the descriptions being illustrated by sketch-maps and plans of workings. The coloured plates give some idea of the brilliancy and exquisite beauty of the original objects, whether these be crystals in their matrix or cut stones. They are scarcely, if at all, inferior in these respects to those in the work of Dr. Kunz already referred to, and higher praise than this can scarcely be given.

Mr. Spencer has been well advised in undertaking the translation, with the aid of his wife, of this important standard work. But the book as it now appears in English dress is much more than a mere translation. Mr. Spencer's familiarity with the bibliography of mineralogy is well known, and he brings to his task, in addition, wide knowledge and experience gained in connection with his work in the splendid national collection of minerals at South Kensington. The author of the work has supplied references to the more important papers which have been issued since the first appearance of the book, and these with many other works, including the valuable annual reports on the production of gem stones by the United States Geological Survey, have been consulted by the translator, many new and valuable facts being added. It would be easy to show, however, that even during the decade that has not quite elapsed since the book was written, much new information has accumulated on many of the subjects dealt with, and to incorporate this, as the translator points out in the case of the diamond, so as to bring the matter quite up to date, would involve the complete re-writing of whole sections. The work is, nevertheless, so complete, trustworthy and up to date that no better guide to the study of gems can be indicated to the student, the worker, or the dealer in these interesting objects.

The general account of precious stones occupies 110 pages, and, as the translator admits, would have to be considerably enlarged if full justice were done to the optical methods of discriminating the mineral species. This, however, would have only a limited

interest for general readers, and therefore is perhaps wisely omitted.

The account of the diamond takes up no less than 150 pages, and, large as is the amount of information collected, there is much more that might with advantage have been included if all the researches of recent years could have been utilised. As it is, the book brings together an enormous mass of details which could only be obtained by long and patient research among widely scattered sources of information. The corundum and beryl gems, topaz, opal, &c., are also very fully treated; but an important feature of this work is the account given of the large number of crystalline minerals, quite unknown to lapidaries and the general public, which are capable of being employed as gems, and as such, are scarcely, if at all, inferior in beauty to the stones which have become famous and are so universally sought after. The varieties of zircon, spinel and tourmaline, which, in the hands of a good lapidary, are capable of yielding gems of exquisite colour and beauty, are well described in this work; while the numerous minerals which more rarely yield transparent and lustrous varieties that can be cut as gems are indicated by the author. In this connection we may point out that even the rare and beautiful varieties of spodumene—known as hiddenite and kunzite—have been included in this edition. The appendix on pearls and coral is interesting, and is necessary to complete the book as a work of reference on the subject. We heartily congratulate the author on having found so competent and judicious a translator, and the translator on having devoted his attention to a work so well worthy of having labour spent upon it

Dr. Farrington's book is on a much smaller scale than Prof. Max Bauer's, but the illustrations are of the same beautiful character. The general account of precious stones has to be compressed into 65 pages, but, as might be expected from the author, the matter is accurate and is very judiciously arranged, while some of the discussions, like those on the superstitions connected with precious stones, are full of interest. The account of the several minerals—not only those so commonly employed as gems, but the rarer ones which can be cut and used in the same way—is, as in the case of Max Bauer's treatise, very full and accurate; but the treatment of each has, from the scope of the work, to be much more concise. The typography and general appearance of the book are of the excellence we are in the habit of finding in the best publications of the American Press J. W. J.

SPECIALISED CHEMISTRY.

Synthetische Methoden der organischen Chemie. By Theodor Posner. Pp. xxxi + 435. (Leipzig: Veit and Co., 1903.)

CHEMICAL literature has assumed such enormous proportions during the last two decades that it is at times almost like seeking a needle in a haystack to endeavour to find whether certain branches of the subject have previously been worked at or not. The difficulty is not so much on account of the variety of books written on the different branches of chemistry, although their number is colossal, but because there are so many journals and periodicals, and because these are so widely distributed.

A chemist who studies or works along a special branch of the subject might hope that all others who work on similar lines would endeavour to publish their results in one or other of a limited number of journals. Actually this is not the case, and as a consequence he must either take in an immense number of periodicals, most of which time will not permit him to glance at, much less study, or he must join some society which takes in these journals. There is, of course, another and very real objection to taking in a vast number of journals—the expense. Those who devote themselves to scientific research are not—generally speaking—endowed with excessive riches. Chemists, therefore, are ready to welcome works which are accurate compilations of scientific research, but even here, *vanitas vanitatis*, the books are out of date almost before they have left the press. However, they are good and useful up to the time at which they were published, and may save a good deal of back reference.

The book before us is such a compilation. When one is engaged on research it is of the greatest possible advantage to be able to consult a work which will tell us at a glance all the most important methods for carrying out this or that operation.

For example, a chemist may be dealing with a substance which he suspects may be a ketone. He is aware that ketones form oximes, hydrazones, semicarbazides, &c., but he may not have at his fingers' ends all the methods which can be employed to bring about these reactions. Dr. Posner's book will be of great help to him in such circumstances.

The book commences with a florid introduction, from which we gather the author's object in writing the book. It is briefly to give a collection of synthetical methods which are of general applicability. Special syntheses for particular compounds are not given, even when they are of great individual importance. In only giving general reactions we think the author was well advised, otherwise the book must have assumed unwieldy proportions.

Under the heading of sulpho-acids we find various methods for sulphonating the hydrocarbons, chloro-compounds, amido-compounds, &c. Dr. Posner rarely condescends to give exact methods of preparation, this, we presume, because very full references are appended at the bottom of each page. This is all very well where one has a large library which contains the books and journals from which the references are taken, but it rather detracts from the value of the work. The great advantage of such a work as this should be its enabling one to dispense with a large number of reference books.

The book is divided into four main parts. The first part deals with the hydrocarbons, and commences with a short description of the different classes of hydrocarbons in the aliphatic series. We then come to a short description of some of the methods of preparation of acetylene and diacetylene. This leads us up to ring hydrocarbons and ring syntheses. Part ii. treats of

the single derivatives of the hydrocarbons, such as the halogen, nitro, amido, &c. The third part is devoted to the study of the poly-compounds. The sugars are here dealt with, and are very fully given. On p. 265 there is a very useful diagram showing schematically the sugar syntheses. The fourth part treats of heterocyclic compounds.

The theoretical introductions at the commencement of the subsections are succinct, and give one an idea of the particular class of substance in a few sentences. A little more space might have been given to the quinones. Under this heading we only find one and a half pages, most of which is devoted to benzoquinone. There are, indeed, other references to quinones in the book, but these do not deal with the modes of preparation.

The compilation of a book such as this requires an immense amount of work, and we think, taking it as a whole, although there are a good many omissions, that Dr. Posner is to be congratulated on having brought out a really useful work. F. M. P.

CHEESE-MITES.

British Tyroglyphidae. By Albert D. Michael, F.L.S., F.Z.S., F.R.M.S., &c. Vol. ii. (London: Printed for the Ray Society, 1903.)

THIS is a second volume only by date and binding; otherwise it is part and parcel of the first, completing the story with all the scientific skill in description and illustration, the critical acumen, and the due proportion of enlivening touches to which attention was directed in these columns two years ago. An annotated list of the principal known or supposed species, not hitherto recorded as British, is a valuable supplement, here thrown in as a free gift beyond the requirements of the title. An interesting addition to the group of cheese-mites is furnished by the new genus and species, *Fusacarus laminipes*, a little fusiform broad-legged acarid discovered by Mr. Michael in moles' nests, sometimes abundant, yet not present in every nest, and never observed upon the mole itself.

Among statements of economic importance may be noted the author's remarks on *Tyroglyphus longior*, Gervais. Of this he says:

"It seems to me to be found in almost all houses upon dried provisions, often swarming in enormous numbers. I have also found it most prolific on hay and fodder, often increasing in countless millions. I once had a sample of hay sent me from a large haystack on a first-class farm in Ireland; the whole stack had practically been destroyed by this Acarus; there were, weight for weight, as large quantities of Acari as of hay in the sample."

On the other hand he vindicates *Histiogaster entomophagus* (Laboulbène) from the reproach, conveyed in its specific name, of devastating entomological collections. Also he agrees with the French acarologists in being hard of belief that the mite which Riley and Planchon called *Tyroglyphus phylloxerae* was at all likely to benefit the French vine-growers by its importation. For one thing, in his opinion, France already possessed the mite in question under an earlier name, and for another, he holds that cheese-mites in general are not at all partial to feeding on insects until the insects are not only dead, but dried, in which condition the dreaded Phylloxera ceases to be a devastator of vineyards. But if Riley's mite does the wine-producer no essential good, *Carpoglyphus anonymus*, Haller, does the wine-vendor positive harm. Anything, indeed, might be expected of a creature so reprobate that it devours the gold size of the very cell in which it is being reared for scientific observation. But this species, which in very Irish fashion has been named "the nameless," further outrages sentiment by being, what the lower animals so seldom are, a set of little drunkards. They defy the great wine-merchants of Paris by increasing in immense quantities inside the wine bottles, "maintaining their position on the surface of the wine without getting drowned by standing on minute pieces of cork," and in this ideal home for inebriates drawing their nourishment from the wine.

Directly in his preface and incidentally elsewhere Mr. Michael directs attention to the unsatisfactory process by which chains are being riveted on zoologists in regard to nomenclature. His remarks are opportune. It may easily come to be supposed that the important compilation of "Das Tierreich" represents on this and some other questions a consensus of opinion. But that is contrary to the fact, the apparent consensus meaning nothing more than a (possibly very reluctant) concession to a supposed need for uniformity, by which the value of "Das Tierreich" itself is not a little likely to be seriously impaired. Moreover, the rules which appear to have been agreed on by the committee of the International Zoological Congress are themselves under more than one grave disadvantage. The report brought up to the highly representative meeting of that congress at Cambridge in 1898 was for some esoteric reason withdrawn from discussion. This opportunity being lost, a larger committee was appointed, but the rules appear to have been settled by only five of the members, Great Britain being left unrepresented at the critical time, through the withdrawal of two members and the absence of a third. After all, perhaps, it is consoling to reflect that rules can only find their ultimate sanction in the practice of the best writers, and work like Mr. Michael's helps one to maintain that British zoology is neither dead nor sleeping, and that it cannot in the long run be left out of account.

OUR BOOK SHELF.

Zoology: Descriptive and Practical. By Prof. Buel P. Colton. Part i. Descriptive. Pp. x+375; 201 figures. Price 4*s.* 6*d.* Part ii. Practical. Pp. xvii+204. Price 2*s.* (London: D. C. Heath and Co., 1904.)

THE author points out in an admirable preface that the study of natural history in schools should follow the seasons, and that animals should be studied in relation to their surroundings. "The study of the relations of animals to their surroundings is a constant investigation of cause," and the pupil has above all to inquire into the meanings of facts. But exercises in classification, in the detailed analysis of types, in

definition making, and so on, are also, he maintains, of great value. The book has been read critically by numerous teachers—some of whom are well known experts—so that it ought to be well-nigh faultless within its limits. The descriptive part begins with insects, leaving difficult groups like Protozoa and Cœlentera to near the end; it is elementary in its mode of treatment, with refreshing breaths of the open air, admirably free from technicalities, and always clear. But the author has tried far too much, and his terseness is repeatedly gained at the expense of accuracy. We do not see the object of attempting a complete survey in a book like this, of dragging in sirenians and brachiopods—the whole show, in short—when the exigencies of space appear to have made it impossible to say about many classes anything worth reading. If the author had been less ambitious of completeness, his book would have been more useful. The practical part of the book, which includes a large variety of material, and mostly consists of simple directions and suggestive questions, is in our opinion a much stronger piece of work. The studies on insects, the crayfish, the earthworm, the turtle, the snake, the rabbit, and many more, considered both as intact living creatures and as objects for anatomical analysis, are admirably conceived and well worked out. The Socratic method is adhered to throughout, and the practical volume will be found very valuable both by teachers and students. It presupposes for the natural history lessons more time and more freedom than is usually allowed in Britain. It should also be noted that there are terse directions on several topics which are rarely alluded to in books on practical zoology, such as skinning birds and mounting insects. Our general impression is that Prof. Colton, who is evidently a skilful teacher, should have expanded and illustrated the *practical* part of his book, incorporating in it all that is personal and distinctive in the *descriptive* part.

J. A. T.

Among the Garden People. By Clara D. Pierson. Pp. viii+236; illustrated. (London: John Murray, 1904.) Price 5*s.*

Our American friends, if not actually ahead, are well up to our level in the matter of encouraging and protecting the native birds of gardens and plantations, and the author has therefore been well advised in arranging for an English edition of the work before us. She has been equally well advised in changing the original title of "Dooryard Stories" for the one this dainty little volume now bears, for few amongst us, we think, are aware that "dooryard" is American for "garden." The American title is, however, still retained in the page-headings.

The book is essentially one for juvenile readers, being written in the form of simply worded stories, in which the birds are made, so far as possible, to tell their own tale according to what may be supposed to be their own ideas. Despite a certain amount of confusion which is almost sure to arise from the misappropriation of the names of familiar English birds for totally different American species, it is certainly an important element in the natural history education of young people that they should be made to understand that the birds of distant lands differ markedly from those of their own, and, as the author observes, it may be a decided advantage to those who visit in mature years the New World to have already made some amount of acquaintance with its feathered denizens.

Not that this volume is by any means absolutely restricted to the birds of American gardens, for it tells us a good deal about some of their four-legged enemies, such as red squirrels and chipmunks. Some of the American names, such as the latter, are explained in a short glossary, in which we are somewhat amused to find the raccoon described as "an American animal, allied to the bear family, but much smaller, and much hunted both for its flesh and its fur." Surely something a little more exact and more to the point could have been supplied by the author's naturalist friends.

The numerous "three-colour" plates are for the most part good and artistic representations of the species they portray, and the volume may be recommended as an attractive gift-book for young people.

R. L.

New Physical Geography. By Ralph S. Tarr, B.S., Professor of Dynamic Geology and Physical Geography at Cornell University. Pp. xvi+457. (New York: The Macmillan Company, 1904.) Price 1 dollar.

As Prof. Tarr says in his preface, the teaching of physical geography is still in its experimental stage. The publication of this volume, which is the third on the same subject by the same author, who now "does not flatter himself that he has produced the ideal," shows there is work yet to be done by teachers of geography. But whether this volume is ideal or not, it is certainly an excellent text-book of the subject. Prof. Tarr begins with a short and not altogether satisfactory chapter on the earth as a planet, and proceeds to a treatment of the lands of the globe. These chapters are followed by descriptions of atmospheric and oceanic phenomena, which are less extended than in the author's previous books, and by an account of the physiography of the United States. The volume concludes with chapters treating of life in its relation to the land, air, and ocean—the last one being called "Man and Nature." Several subjects usually included in books on physical geography are relegated to appendices, and among these may be mentioned: revolution of the earth, latitude and longitude, tides, magnetism, and meteorological instruments. There are 568 illustrations, most of which are of a striking and instructive character.

Quiet Hours with Nature. By Mrs. Brightwen. Illustrated by Theo. Carreras. Pp. xvi+271. (London: T. Fisher Unwin, 1904.) Price 5*s.*

Mrs. Brightwen writes in a way that is sure to gain the attention of young people. Her sketches are in no sense formal scientific descriptions of the familiar animal and plant life of this country, but they are likely to arouse an interest in natural history and to lead readers to observe for themselves. The book shows clearly how much worth close inspection and study an English garden contains, and rightly indicates there are common phenomena which still remain unexplained. The book is well illustrated and deserves to be a favourite with boys and girls.

Le Monde des Fourmis. By Henri Coupin, Lauréat de l'Institut, &c. Pp. 160. (Paris: Delagrave.)

This is a small popular book relating to the habits, architecture, and intelligence of ants, and largely consists of extracts from the works of Huber, Forel, Lubbock, Moggridge, and other well known writers, chiefly French and English. The subject of the book cannot fail to interest those previously unacquainted with it, but it contains little that will not be familiar to everyone who has read any recent works on ants. It is very inferior to such a book as Ernest André's "Les Fourmis," published in 1885, but we believe that this has been out of print for some time. We may add that M. Coupin's book contains a few illustrations of a very inferior description.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Life-history of Radium.

IN a letter under the above title in NATURE of May 5, Mr. Whetham brings forward some results dealing with the hypothesis that radium is being produced from uranium. May I be permitted to state that I have been engaged during the last twelve months in an experimental examination of this hypothesis? In the paper in which the suggestion was made that radium may be being formed by the disintegration of a parent element possessing heavier atomic weight (Rutherford and Soddy, *Phil. Mag.*, May, 1903, p. 587), this sentence occurs:—"The point is under experimental investigation by one of us, and a fuller discussion is reserved until later." Mr. Whetham's letter makes it desirable that the results that have been obtained during the past year should be published.

Twelve months ago I purified a kilogram of uranium nitrate until the quantity of radium present was less than 10^{-13} gram. This was the limit of detection by means of the electroscope employed, using the maximum or equilibrium amount of accumulated radium emanation as the test for the presence of radium. It was arrived at by direct comparisons with the emanation from a standard milligram of radium bromide, by subdivision until its presence could no longer be detected. Unfortunately, owing to the large amount of radium in the laboratory, subsequently introduced for the purpose of the helium research, the electroscopes have been affected, and it is not possible at the present time to be sure of such minute effects as originally. But it may be stated that less than 10^{-11} gram of radium has accumulated in the kilogram of uranium during the past twelve months. This practically settles the question so far as the production of radium *from uranium* is concerned.

In a paper read recently before the Royal Society by Sir William Ramsay and myself, an experimental determination of the rate of change of radium was given. It was shown that rather less than one-thousandth part changes per year. The rate of change of uranium may be taken as a million times slower, since its radio-activity is a million times less; so that, in one kilogram of uranium nitrate, about 5×10^{-7} gram would change per year. The quantity of radium produced was less than 10^{-11} gram, so that the conclusion is arrived at that if uranium changes into radium, less than one-ten thousandth part of the theoretical quantity is produced during the first year's accumulation.

The result, of course, may be explained by assuming the existence of intermediate forms between uranium and radium. But from a general consideration of the whole question from the point of view of the disintegration theory, several such hypothetical forms, each with an extended life, must be assumed. So that unless modifications are made in the theory, which at present are not justifiable, the evidence may be taken as indicating that uranium is not the parent element of radium. The experiments will be continued from year to year with the kilogram of uranium nitrate. But as I am leaving England immediately, and shall be away several months, I take the opportunity of presenting the results of the unfinished research, and hope at a later date to give a fuller account.

FREDK. SODDY.

University College, Gower Street, W.C.

IN their communication to the Royal Society of April 28, Sir William Ramsay and Mr. Soddy by direct measurements determine the rate of decay of radium as one thousandth of the mass per annum, giving as the average life of the radium atom about one thousand years.

This rapid rate of decay, of course, renders it quite out of the question to assume that in the radium now existing on the earth we are dealing with the residue of a larger quantity reduced by decay to its present amount. If we carry backwards so great a rate of change we, in fact, arrive at the existence of such large amounts quite a few thousand years ago as to postulate a red hot earth almost within historical times. We are thus either compelled to assume that the rate of transformation observed does not apply generally to terrestrial radium, but only to radium separated by chemical treatment from pitchblende, or that the existing store of radium is derived by steady supply from some substance of greater atomic weight. The first hypothesis, in view of what is known as to the intimately atomic nature of radio-activity, may be dismissed.

That the probable source of radium is uranium is advocated by Prof. Rutherford in his book on radio-activity. From a conversation with Sir Oliver Lodge I gather that he also considers this not improbable. The reasons for it need not be given here.

Now if radium is derived from pitchblende, the rate of change of radium is a measure of the rate of change of pitchblende, supposing a steady state of supply and loss has been attained. This last condition I think we are entitled to assume, although doubtless from the mathematician's point of view a perfect equality would be improbable. But I will quote Prof. Rutherford ("Radio-activity," p. 334):—"Since radium has a short life compared with that of uranium the amount of radium produced should reach a maximum after a few thousand years when the rate of production of fresh radium—which is also a measure of the rate of change of uranium—balances the rate of change of that product."

Let us now assume as an approximation that from 1000 kilos. of uranium the yield of radium under the most favourable conditions would be one decigram. It may here be observed that the fact of pitchblendes varying in their content of radium is only what is to be expected under the conditions of preservation of the ore, exposed as it is to chemical attack, or, as Prof. Rutherford points out, to the action of percolating water. We have in seeking to learn the content of radium for our present purpose to take the maximum observed.

The one decigram of radium transforms into substances of lesser atomic weight at the rate of one-tenth milligram per annum. Now this is also the annual supply from 1000 kilos. of uranium. In other words, the uranium breaks down at the rate of $1/10^{10}$ part of its mass per annum. The average life of the uranium atom is according to this ten thousand million years.

In determining this average life from so short a period of observation we, of course, make the assumption that the death rate observed is an average one, and that a steady state is attained truly founded on the mean longevity of a vast number of individuals of varying ages, varying rates of loss of corpuscular temperature as well as of varying amounts of initial corpuscular energy, such conditions as would attend material evolution according to Prof. J. J. Thomson's fascinating book "Electricity and Matter." Similar assumptions must be made before we could deduce the average longevity of a vast population from a short period of observation of the death-rate.

On these assumptions an interval of time is indicated which may be considered a minor limit to the antiquity of matter in our part of the universe. For if the average life is really 10^{10} years, must we not assume that some of the atoms now expiring as uranium were existing ten thousand million years ago? Geological time, as we guess it, is but little more than a moment in the being of so great an era—as thirty-six seconds is to an hour.

Whether we will ever be able to obtain direct *proof* of so remote an antiquity is impossible now to say, but it is remarkable that the rate of change of thorium to thorium X affords the same average longevity for the atom of thorium as we arrive at on the data above for uranium, or again from the known rate of change of uranium to uranium X. Thus Rutherford gives 10^{-16} to 10^{-17} as the change-rate per second to thorium X. The change-rate 10^{-10} for a year's disintegration will be found to lie between these limits.

Behaviour of Radium Bromide Heated to High Temperatures on Platinum.

IT may be of interest to record that radium bromide obtained from Schuchardt, of Görlitz, and stated to be pure, melts at 728° C. This number is arrived at by observations on minute specks of the substance heated upon the platinum ribbon of the meldometer.

At higher temperatures—up to 1600°—there is every appearance of decomposition, a quiescent glass finally remaining on the hot platinum. After the experiment it is found that the platinum is deeply pitted, and that in some of the pits the limpid glassy substance remains imbedded. This glass is insoluble in hot or cold water or in HCl even after prolonged immersion in the hot acid. It can be removed only partially from the platinum by scraping. Its refractive index is low.

The pitting would most readily be accounted for by supposing a platinum bromide formed, but what, then, becomes of the radium? Is an alloy formed? The ribbon is found to be still radio-active after the experiment, but feebly so. I have not made quantitative observations for possible recovery of activity.

J. JOLY.

Trinity College, Dublin, May 7.

Electromotive Force between Two Phases of the Same Metal.

FROM the microscopic study of the changes which take place in metals in hardening and annealing, I had been led to the conclusion that metals may occur in two phases, a hard or amorphous phase and a plastic or crystalline phase (*Proc.* Roy. Soc., vol. lxxii. pp. 218, 232). In seeking for independent evidence of this, it occurred to me to try if there existed a measurable electromotive force between the two phases, and I have now obtained definite proofs that this is the case in all the metals which have been tested. In the case of silver, a thermo-junction consisting of a hardened and an annealed wire gave an E.M.F. of 128 micro-volts at a temperature of 250° C. This temperature appears to be near the transition point, and beyond this the E.M.F. falls to zero, as the wires are then both in the same phase. Further experiments on the subject are in progress, and the results will be published in due course.

GEORGE BEILBY.

11 University Gardens, Glasgow, May 7.

A Simple Method of Showing Vortex Motion.

IF a little aqueous fluorescein be placed in a glass tube drawn out to a capillary bore, and supported vertically over a tall cylinder of water, so that the orifice is just beneath the surface, the fluorescein will descend through the water in a fine stream.

If the water be quite tranquil and free from any rotatory motion, this stream will continue straight, unbroken, and clearly defined to the bottom of the jar.

Let a tap be given to the stand supporting the tube; a slight swelling will appear on the issuing stream and gradually increase in size, widening as it goes, while the part immediately behind it becomes more and more slender, and finally parts altogether.

The separated portion continues to widen, and the velocity of the centre being greater than that of the edge, it acquires a motion of rotation, and becomes a perfect vortex ring. If a succession of taps be given to the stand, a series of such rings are formed in regular order. As their velocities diminish, their cross sections increase; they alternately pass through one another, and their motion can be observed with great ease on account of the slowness with which it takes place. I do not know if this method of producing vortices is new or not, but at all events it possesses the merit of simplicity.

Napier's Logarithms.

STUDENTS interested in this subject may be recommended to consult "The Construction of the Wonderful Canon of Logarithms," by John Napier, Baron of Merchiston; translated from Latin into English, with notes and a catalogue of the various editions of Napier's works, by William Rae Macdonald, F.F.A. (William Blackwood and Sons, Edinburgh and London, 1889.)

G. B. M.

THE EXCAVATOR'S VADE MECUM.[1]

IF any man living is qualified to write a book on the subject of excavating it is Prof. Petrie, than whom no one has had a longer and wider experience or more consistent success. And, as a perusal of these pages will show, the work of excavation is something more than the mere overturning of earth with the spade and extraction of such treasures as may be concealed beneath it. There is not only the organisation and direction of labour, with all the knowledge of human—and especially of the Oriental—nature that it involves, the adaptation to physical conditions, the comprehension of the history and geography of the country, and, last but not least, the unerring eye for the disposition of cemeteries or temple sites which is almost an instinct rather than a matter of experience. The ideal excavator must, in addition, be a skilful draughtsman and photographer; he must have some knowledge of chemistry, geology, mechanics, and surveying, besides—*cela va sans dire*—the archæological knowledge which enables him to identify, estimate, and classify on the spot the results of his researches.

That the writer of this book fulfils perfectly in his own person all these requirements, he would probably be the first to deny; but his long experience has given him a title to speak, as it were, *ex cathedra* on all such subjects, and though the work deals almost exclusively with excavation from an Egyptian point of view, it will henceforth be indispensable for its practical value to all investigators in any part of the world. In fact, it contains so much practical advice on every possible head that one may fancy the would-be follower of Prof. Petrie somewhat staggered at the task set before him. The apparatus laid down as essential for preservation and packing of objects alone would seem to necessitate the transport of a whole Whiteley's or Gamage's to the Egyptian deserts. We have been sufficiently curious to compile a list of materials named in these two chapters. They include barrels, zinc trays, brushes of various kinds, paraffin wax, tapioca water, emery paper, gelatine, benzol, silicate solution, glycerine, nitric acid, fuller's earth, sheets of glass, plaster, ammonia, hydrochloric acid and other chemicals, in addition to tools and other more obvious necessities. But perhaps the author regarded this list as a counsel of perfection, as he gives a much shorter one on pp. 112–113.

Seriously, however, all such hints are extremely valuable, and provide for every contingency and every difficulty that may arise in the course of an excavation. The only valid objection that might be taken to them is that much of what is said is perfectly obvious to a person of average intelligence, and that plenty of good work on these lines has been done elsewhere besides in Egypt. However, Prof. Petrie takes his subject seriously and with genuine enthusiasm, and his system affords a welcome contrast to that of the excavator for mere pleasure or for unblushingly commercial ends, to whom archæological results are nothing, and whose labours therefore confer no benefit on any save himself. If we may venture on a word of criticism in general, we may say that he is inclined to be somewhat too severe on the work done by museums and by the stay-at-home archæologist. The explorer, as Mr. Hogarth well pointed out in his charming "Wandering Scholar," can never supply the place of the scholar; happy is he who combines both capacities in his own person, as it has been given to few to do; but the one will always be complementary to the other. Hence we think Prof. Petrie too much inclined to regard excavation (even with all its con-

[1] "Methods and Aims in Archæology." By W. M. Flinders Petrie. Pp. xviii+208; with 66 illustrations. (London: Macmillan and Co., Ltd. New York: The Macmillan Co., 1904.) Price 6s.

comitant labours) as in itself comprising archæology. This cannot be; the excavator supplies the materials, and it rests with him to supply them in a scientific and workmanlike manner; but the years of study which they often demand must be the lot of the student, who, we can assure our author, would often be only too grateful if he had the chance of combining both functions.

The subject is distributed over fourteen chapters, beginning with the qualifications of the excavator himself, the experience or instinct necessary for identifying sites or finds, and three chapters dealing with the actual work in the field—the labourers, methods of turning and raising earth, and recording on the spot. Then follow successive chapters on copying and drawing, photography, preservation of objects, packing, and finally publication. The last four are of a more general nature, dealing with the systematising of results, the nature of archæological evidence, the ethics of archæology, such as the rights of the State, and lastly, the fascination of history by way of epilogue. Space forbids a detailed description of the many interesting points and valuable suggestions contained in these chapters, but the book will be found eminently readable even by those who cannot hope to wield the spade.

FIG. 1.—The clearing of the Osireion at Abydcs, Egypt.

We cannot, however, lay it down without a feeling that the author is throughout too prone to disregard the work of other archæologists; for instance, on p. 123, where he complains that no one since Montfaucon (whose work, by the bye, is singularly useless) has attempted the collecting of series of objects in a *corpus*. Has he never heard of M. Reinach's invaluable *répertoires* of Greek sculpture and vases? Is he not aware that the German Archæological Institute is issuing a magnificent publication of Greek terracottas? And is not a *corpus* of coins under consideration? We purposely pass over the growing number of museum catalogues of all kinds, which if not *corpora*, are still a step in that direction.

The book is illustrated by sixty-six photographic or outline reproductions, of sites, operations, and monuments, the titles of which are at times somewhat oddly arranged (*e.g.* Figs. 36–37), but they are clear, well chosen, and instructive. We have selected for reproduction the frontispiece, representing the clearing of the Osireion at Abydos by a chain of boys with baskets, extending more than forty feet down. The index errs if anything on the side of redundancy; such headings as "carefulness, means of securing"; "chain of boys"; "choice of facts"; "finest lines in drawing"; "list of plates"; "red paint"; "wet squeezes," are not only superfluous, but contrary to all the rules of good indexing. H. B. W.

PROF. A. W. WILLIAMSON, F.R.S.

ON Friday last, May 6, there passed away, full of years and of honour, Alexander William Williamson, one of the most notable of British chemists, and one who, in the heyday of his intellectual activity, exercised a remarkable influence on the development of chemical theory. He had been in failing health for some years past, and such was the seclusion in which he lived of late that his tall manly form and striking features were practically unknown to the younger generation of chemical workers. Indeed, after his retirement, in 1889, from the position of Foreign Secretary of the Royal Society, which he held for some sixteen years, and after the termination of his active connection with the British Association for the Advancement of Science, of which he was treasurer for many years, he rarely visited London, and unless on an occasion when it was represented to him that his influence and the weight of his authority were needed in support of some reform, it was difficult to induce him to revisit the scenes of scientific activity in which he had himself played so strenuous and so eminent a part. Until within the last few years, when his mental powers were obviously failing, he continued to take a keen interest in the progress of science, and it was easy to engage his attention on the broad general lines of its development.

Williamson's mind was cast in a large mould, and, although at times he could occupy himself with even small details if he recognised that these were significant or possibly fruitful of theoretical consequence, he was apt to be impatient of the somewhat tiresome minutiæ with which modern chemical literature abounds. He was probably never a great reader of such literature at any period of his career, and his

physical infirmity made it increasingly difficult for him to keep himself informed. At the same time the very limitation of his physical powers, his partial paralysis, and his poor eyesight, probably conduced to his eminence as a speculative thinker. He was gifted with a strong logical mind, and was an acute reasoner, and a clear, vigorous, and independent thinker, capable of broad and striking generalisation. Knowledge, we know, dwells in heads replete with thoughts of other men, wisdom in minds attentive to their own. Except by personal contact, Williamson was largely debarred from the knowledge of other men's thoughts; by the very circumstances to which allusion has been made he became more attentive to his own. Like most original thinkers he was somewhat tenacious of opinions, and apt to be dogmatic in their utterance. His beliefs were too hardly won to be lightly discarded. But although at times impatient of contradiction, he had too strong a regard for truth, was too sincere and broad-minded a man to persist in any opinion, if its unreasonableness was made clear to him. Like Carlyle, his philosophy was largely swayed by his emotions, and like Carlyle's, his judgments on men and things were apt to be tinctured by the mood of the moment—a fact which may serve to account for seeming inconsistencies in their expression.

He had a high sense of duty, and of the responsibilities of his position as a representative man of science. Although, like many strong men, fond of power, he was in no sense a self-seeking man, and was contemptuous of the artifices by which smaller and more ambitious men seek to gain preferment.

Williamson was born at Wandsworth on May 1, 1824; hence he had just completed his eightieth year at the time of his death. Much of his early life was spent on the Continent. He began the study of chemistry under Gmelin at Heidelberg, in the old cloisters which formerly did duty as class rooms and laboratory, but soon joined Liebig at Giessen. Whilst at Giessen he published, so far back as 1845, his first paper on "The Decomposition of Oxides and Salts by Chlorine," in which he determined the conditions of production of hypochlorous and chloric acids, and the cause of the difference in the mode of action of chlorine upon alkalis and alkaline earths, and upon salts. The main outcome of this paper has long since been worked into the text-books. It is of interest as throwing light upon the theory of the action of bleaching solutions. The experimental material for a short paper on "Ozone" was likewise accumulated at Giessen. In this paper, which also appeared in 1845, Williamson concluded that the peculiar properties belonging to the oxygen set free by the agency of the electric current are produced by the admixture of a *peroxide or acid of hydrogen*, whereas by the action of phosphorus on atmospheric air the same substance is *not* produced. His surmise that a compound of hydrogen and oxygen existed possessing some of the characteristic properties of ozone but dissimilar from Thénard's hydrogen peroxide has not been established by subsequent investigation.

At about this time Williamson took his degree, and in 1846, whilst still at Giessen, published an important paper on "The Blue Compounds of Cyanogen and Iron," which probably contains more determinative analytical work than any other of his memoirs. In it he describes the formation of prussian blue in different circumstances, and the influence which these exercise on its composition, giving particular attention to the presence of potassium, which materially affects the colour and dyeing power of the product.

These, with two short papers, one relating to the theory of ozone, and another on the constitution of œnanthol, which he published in Liebig's *Annalen*, comprise the outcome of the Giessen period. He then passed on to Paris, where he came under the influence of Comte. It is hardly to be supposed that a man of his temperament, and in such surroundings, could remain wholly unaffected by the events of 1848. His position, however, was made secure by Graham, who came over to Paris to offer him the chair of practical chemistry in University College, to which he was appointed in 1849, and where he continued to teach for thirty-eight years.

In 1850 Williamson published his epoch-making paper on the "Theory of Ætherification." It was first read to the chemical section of the British Association at the Edinburgh meeting of August, 1850, and in its original form as "communicated by the author" occupies about seven pages of the *Philosophical Magazine*. Certainly no chemical paper of equal length ever exercised so profound an influence on contemporary thought. This memoir, although frequently referred to, is probably seldom read by the chemical student. And yet written more than half a century ago there is scarcely a term in it which needs alteration to bring it into harmony with modern chemical terminology or present day doctrine. It is a model of concise reasoning, founded upon happily devised experiment. Williamson clearly traces for us the genesis of the idea which led him to his capital discovery. His original intention was not to elucidate the theory of the manufacture of ether; he says his object in commencing his experiments was to obtain new alcohols by substituting carburetted hydrogen for hydrogen in a known alcohol, and for this purpose he acted upon sodium ethylate with the iodide of the carburetted hydrogen which was to be introduced in the place of that hydrogen—an expedient which he says he hopes may render valuable services on similar occasions. To his astonishment the compound thus formed had none of the properties of an alcohol—it was nothing else than common ether, $C_4H_{10}O$. This simple observation threw a flood of light upon the relations of alcohol and ether, which Williamson proceeded to develop by a train of reasoning, and to prove by a series of experiments which are now among the commonplace observations of every lecturer in organic chemistry wherever the science is taught. Williamson not only illustrated these relations by arguments and proofs which are absolutely unassailable, but by a course of reasoning which instantly riveted the attention and secured the adhesion of the whole chemical world, he demonstrated the true process of etherification, and thereby reconciled the teaching of apparently irreconcilable facts. It must have been with a special gratification that the young man of twenty-six penned the following lines, which happily summarise the position he had attained.

"Innovations in science frequently gain ground *only* by displacing the conceptions which preceded them, and which served more or less directly as their foundation; but, if the view which I have here presented be considered a step in our understanding of the subject, I must beg leave to disclaim for it the title of innovation; for my conclusion consists in establishing the connection and showing the compatibility of views which have hitherto been considered contrary; and the best possible justification of the eminent philosophers who advocated either one of the two contending theories, is thus afforded by my reconciling their arguments with those of their equally illustrious opponents." An observation no less tactful than true.

The paper is epoch-making in more senses than one. In it Williamson not only foreshadowed his adherence to the doctrine of types which in his subsequent teaching he did so much to elucidate and extend, but he

likewise seeks to import into the general process of chemical action the conceptions of dynamics. The simple words with which he concludes his paper sound somewhat archaic to-day, but fifty-four years ago they must have startled the members of Section B. "In using the atomic theory, chemists have added to it of late years an unsafe, and as I think, an unwarrantable hypothesis, namely that the atoms are in a state of rest. Now this hypothesis I discard, and reason upon the broader basis of atomic motion."

Williamson was not a prolific writer, and his fame mainly rests upon his work of this period and upon what he achieved during the first ten years of his professorial activity. He published comparatively little between 1854 and 1864, but under the stimulus of the new movement, he took an active part in the formulation of what is still current doctrine, and produced a series of papers on the principles of chemical classification, valency, and nomenclature which exercised a powerful influence on chemical teaching in this country.

Williamson was elected into the Royal Society in 1855, and served on the council from 1859 to 1861, again from 1869 to 1871, and for a third time from 1873 to 1890, during which period he acted, as already stated, as foreign secretary. In 1889–1890 he was made a vice-president. In 1862 he received a Royal medal. He was twice president of the Chemical Society—viz., in 1863–65 and again in 1869–71, and was one of the six presidents who had been fellows of the Society for upwards of half a century who were present at the memorable banquet in 1898. He was largely instrumental in establishing the present series of abstracts of foreign chemical literature which form so valuable a feature of the *Journal* of the Chemical Society.

In 1873 he was president of the British Association.

His merits as a man of science received wide-spread recognition. He was an honorary graduate of Dublin, Edinburgh, and Durham, a member of the Institute of France and of the Berlin Academy, and of many scientific societies on the Continent and in America.

T. E. THORPE.

ÉMILE DUCLAUX.

IN the death of Émile Duclaux science has lost one of her most devoted and brilliant workers. His career has formed the principal link between the bacteriology of the present day, and what may be called the heroic period in the history of micro-biology which followed on the unveiling, by the genius of Pasteur, of the secret of fermentation, and the consequent opening out of avenues through which innumerable problems could be successfully attacked.

The Pasteur Institute will in particular mourn its loss, for, owing to the charm of his personality and the extraordinary catholicity of his scientific enthusiasms, he was a worthy successor to the great leader, and the continuance of that brotherliness which was such a striking feature among the little community of scientific investigators in the Rue Dutot must in considerable measure be attributed to his influence.

Duclaux was born at Aurillac, on June 24, 1840. He was not a son of fortune, and it was only by dint of hard struggle and a determination which was capable of much self-denial that he succeeded in becoming a *Normalien* in 1859. At the Ecole Normale he studied principally chemistry and physics, and left the school as *Agrégé* in 1862.

At that time Pasteur, who had returned to the Ecole Normale as director of scientific studies, had recently established the positions of Agrégés préparateurs, whereby an able and earnest young graduate might remain for a few years as a research-assistant to one of his masters.

For some three years Duclaux remained préparateur to Pasteur, and was his first lieutenant during the celebrated investigations into the causes of diseases in wine and into the silkworm disease, which had nearly ruined some of the Departments of France.

In 1865 he became Docteur ès Sciences, presenting a thesis upon fractional distillation. In the same year he was appointed a professor at the *lycée* in Tours, and during the following year became acting professor of chemistry at Clermont. It was at Clermont that Pasteur stayed with Duclaux during the troublous times of the war, and it was here that the intimacy and affection which ceased only at the death of Pasteur was established between them. It was at Clermont, also, that he numbered among his students Roux, whom he introduced to Pasteur.

From Clermont, Duclaux went to Lyons as professor of physics, where he remained until he accepted, in 1878, the chair of physics and meteorology at the Institute Agronomique in Paris. In 1886 he became professor of biological chemistry at the Sorbonne, which position he held until his death. When the Pasteur Institute was completed, he transferred his classes to the Rue Dutot. At the death of Pasteur, Duclaux was elected to succeed him as director, and for the last nine years the great work of the Institute has been developed under his guidance. He, however, has not taken any direct part in that portion of its activities dealing with infective diseases, but has confined himself more particularly to the chemical and industrial side of micro-biology.

When one considers the scientific work of Duclaux, the first and most striking point is the wide range of subjects it includes. Trained as a chemist and physicist, he has occupied chairs in both these subjects, and has published a not inconsiderable number of original researches in the domains of pure chemistry and physics. At the same time his most important work was biological. Like Pasteur, he was a chemist who worked at biology, but principally at that department of biology dealing with the physiology of micro-organisms and the chemistry of enzymes, and he brought his training in the exact sciences to bear upon investigations of a biological character, with the greatest success.

The list of his original contributions to scientific journals contains upwards of eighty papers, and includes papers on molecular physics, chemistry, meteorology, physiology of digestion, enzymes, vegetable physiology, bacteriology, and technological papers on milk, butter, wine, sericulture; and he is also the author of several books. In "Ferments et Maladie" and "Le Microbe et la Maladie" he gave popular expositions of the results achieved by the Pasteurian method, and the complete change thereby produced in the standpoint from which infectious diseases were regarded.

In 1896, Duclaux published his "Pasteur, Histoire d'un Esprit," which deals with the researches of the great master from first to last, pointing out the condition of knowledge on the various subjects before Pasteur had brought them, one by one, under the influence of his imagination and accurate experimentation. This forms one of the most brilliant descriptions of the operation of scientific method in unravelling the relationship of phenomena; its perusal might well form a portion of the education of every student of science.

The most important of Duclaux's published books is the "Traité de Microbiologie"—the four volumes of which appeared during the years 1898 to 1901—each chapter of which bears the stamp of the author's individuality, and contains many original observations not

published elsewhere. "L'Hygiène sociale" embodies a series of lectures given at the École des hautes Études sociales, in which he points out forcibly that the development of our knowledge regarding the causation of disease has devolved upon us new responsibiliities as individual citizens, and in which he advocates an intelligent propagandism rather than legal insistence.

On one occasion Duclaux felt himself constrained to leave the peaceful search after truth which he had been pursuing all his life in his laboratories, and to enter upon the turmoil of the public platform. This was on the occasion of the Dreyfus case, when, thinking the cause of truth was imperilled, he, with complete disregard of all personal considerations, and, as it happened, with most disastrous consequences to his health, threw himself into that fierce struggle with invincible ardour. He, with Zola, Grimaux, and some other *intellectuels*, founded the Ligue des Droits de l'Homme, and it was whilst addressing a meeting of this League that he was seized with an attack of apoplexy. He made a slow recovery, and regained sufficient health to resume his work at the Institute, but has now succumbed to a second seizure from which he never regained consciousness.

Owing to the versatility of his genius and the wide field of scientific subjects which occupied his attention during a very active life, it is difficult to form an adequate estimate of the importance of his scientific work. It will be, perhaps, on account of his researches into the ferments and the chemical processes associated with the life and activities of micro-organisms that he will be best remembered by the world of science; but for those who have had the privilege of being his pupils and associates it will be the memory of the kindly guide and critic, whose enthusiasm was a continual spur to effort, and whose ideas were ungrudgingly at the disposal of every disinterested inquirer into truth, that will remain for ever foremost. CHARLES J. MARTIN.

SIR H. M. STANLEY.

THE death of Sir H. M. Stanley on Tuesday, at sixty-three years of age, deprives the world of a man of action, and geography of one of its greatest pioneer explorers. It can truly be said that he changed the map of Africa by the results of his expeditions, and his picturesque narratives created public interest in the problems of African exploration.

Stanley's adventures in Central Africa while engaged in the search for Livingstone attracted great attention, and his famous book, "How I Found Livingstone," in which the expedition is described, has become a classic work of travel. Commissioned to find Livingstone, of whom nothing had been heard for two years, Stanley reached Zanzibar in January, 1871, and on November 10 of the same year met the explorer at Ujiji, on Lake Tanganyika, where Livingstone had just arrived from Nyangwe. The two travellers explored together the north end of Tanganyika, and proved conclusively that the river Rusizi flowed into and not out of the lake, and that Tanganyika had no connection with the Nile system. In February, 1872, Livingstone started on the journey from which he never returned, and Stanley made his way back to Europe.

In 1874, Stanley left England for the expedition to Central Africa which has immortalised him. The writer of the obituary notice in the *Times*, from which some of the particulars here given have been derived, points out that little more than the position of Victoria Nyanza was then known; its shape was all wrong; our knowledge of Albert Nyanza was incomplete; Lake Tanganyika was imperfectly defined; and nothing was known of the region that lies between Lakes Albert and Tanganyika. Stanley's expedition changed all that. He proceeded from Bagamoyo west and north to Victoria Nyanza, tracing a river which he believed (erroneously, we now know) was the remote source of the Nile. He circumnavigated the lake, and for the first time proved to satisfaction that it was one great lake and not a group of small lakes, and that its shape was very different from that laid down in Livingstone's map. Westwards to Muta Nzige, as Lake Albert is called by the natives, Stanley and his great following marched. They struck a bay (Beatrice Gulf), which is now recognised as part of a southern lake, afterwards named by Stanley Lake Albert Edward. Important rectifications and additions were made in the country lying between Victoria Nyanza and the lakes to the west, and thence south to Ujiji. Stanley circumnavigated Tanganyika, rectifying its contour, and proving conclusively that the lake had an outlet in the river Lukuga.

Leaving Nyangwe in November, 1876, Stanley reached Boma, near the mouth of the Congo, in August, 1877. This journey across Africa lasted two years and nine months. The results to geography were certainly immense; it is doubtful if on any other single expedition so much had been done to fill up the great blank in the map of Africa. The narrative of this expedition was given by Stanley in "Through the Dark Continent."

The magnitude of Stanley's discovery we are only now realising, when the multitude of mighty tributaries north and south are being opened up, and we are able to form an estimate of the vast basin of the Congo.

Stanley had scarcely landed in Europe, in 1878, when the King of the Belgians solicited his aid in the opening up of the Congo. In the following year he returned to the Congo; and this was the beginning of what really soon became the Congo Free State, under the sovereignty of the King of the Belgians.

In 1887, Stanley went again to Africa—this time in search of Emin Pasha. Emin was found, but the expedition met with several disasters. Finally, marching through new country, exploring the Semliki River, Mount Ruwenzori, and Lake Albert Edward, Stanley and his followers made their way by the south of the Victoria Nyanza to the coast, he reaching Zanzibar on December 6, 1888, leaving Emin behind on the mainland.

On this expedition Stanley succeeded in solving some important problems in the hydrography of Africa and adding much to our knowledge of its geography. Among the geographical results were the discovery of the Semliki River, which issues from Lake Albert Edward and enters the south end of Lake Albert Nyanza, the Ruwenzori range between these two lakes, and the south-western extension of Lake Victoria. The results of this expedition are described in the volume "In Darkest Africa."

Stanley has been termed "the Bismark of African exploration," and in many respects the comparison is not inappropriate; for the work he accomplished united into one great whole the *disjecta membra* of African exploration, and it was carried out with firm nerve and unflinching will.

INTERNATIONAL ASSOCIATION OF ACADEMIES.

THE following is a list of the delegates who, according to the latest advices, will attend the General Assembly of the International Association of Academies, to be held at the Royal Society's Rooms at Whitsuntide:—

Amsterdam.—Koninklijke Akademie van Wetenschappen, Prof. H. G. van de Sande Bakhuyzen and Prof. M. J. de Goeje. *Berlin.*—Kgl. Preussische Akademie der Wissenschaften, Prof. H. Diels, Prof. W. Waldeyer, Prof. W. von Bezold and Prof. R. Pischel. *Brussels.*—Académie

Royale des Sciences, Prof. Léon Fredericq and Prof. Chevalier Edouard Descamps. *Budapest.*—Magyar Tudomanyos Akademia, M. Charles Than and M. Ignatius Goldziher. *Christiania.*—Videnskabs Selskabet, Prof. H. Mohn and Prof. G. Guldberg. *Copenhagen.*—Kongelige Danske Videnskabernes Selskab, Prof. J. L. Heiberg and Herr Paulsen. *Göttingen.*—Königliche Gesellschaft der Wissenschaften, Prof. E. Ehlers, Prof. F. Leo, Prof. F. Kielhorn and Prof. E. Riecke. *Leipzig.*—Kgl. Sächsische Gesellschaft der Wissenschaften, Prof. Dr. Flechsig and Prof. Dr. Credner. *London.*—Royal Society, Sir William Huggins, Mr. A. B. Kempe, Prof. Larmor, Mr. Francis Darwin, Sir Michael Foster, Lord Kelvin, Prof. Armstrong, Mr. George Darwin, Prof. Forsyth, Sir David Gill, Prof. Liversidge, Sir Norman Lockyer, K.C.B., Prof. Schuster, Dr. Waller, Sir William Ramsay, K.C.B., Mr. Bateson and Prof. Milne. *London.*—The British Academy for the Promotion of Historical, Philosophical, and Philological Studies, Lord Reay, Right Hon. James Bryce, Sir R. C. Jebb, Dr. Caird, Sir C. P. Ilbert, K.C.S.I., Right Hon. Sir A. Lyall, G.C.I.E., K.C.B., and Prof. Rhys Davids. *Madrid.*—Real Academia de Ciencias, Señor José Echegaray and Prof. Santiago Ramon y Cajal. *Munich.*—Kgl. Bayerische Akademie der Wissenschaften, Prof. Ferdinand Lindemann and Prof. Karl Krumbacher. *Paris.*—Académie des Inscriptions et Belles Lettres, M. Georges Perrot, M. Emile Senart, M. le Comte de Lasteyrie, M. H. Omont, M. M. Collignon and M. J. Lair. *Paris.*—Académie des Sciences, M. Mascart, M. Gaston Darboux, M. Henri Poincaré, M. H. Moissan, M. A. de Lapparent and M. A. Giard. *Paris.*—Académie des Sciences Morales et Politiques, M. Georges Picot, M. Paul Leroy-Beaulieu, M. Glasson, M. le Comte de Franqueville, M. Boutroux, M. le Baron de Courcel, M. Henri Joly and M. Paul Meyer. *Rome.*—R. Accademia dei Lincei, Prof. Giacomo Ciamician and Count Ugo Balzani. *St. Petersburg.*—Académie Impériale des Sciences, Msr. A. S. Famintzin and Prof. C. H. Salemann. *Stockholm.*—Kongl. Vetenskaps Akademien, Prof. G. Retzius and Prof. S. E. Henschen. *Vienna.*—Kaiserliche Akademie der Wissenschaften: A.—Mathematish-naturwissenschaftliche Klasse, Prof. Viktor von Lang, Prof. Sigmund Exner, Dr. Edmund Mojsisovics, Edler von Mojsvar, and Prof. Heinrich Obersteiner. B.—Philosopisch-historische Klasse, Prof. Theodor Gomperz, Prof. Joseph Karabacek and Prof. Leopold von Schroeder. *Washington.*—National Academy of Sciences: its foreign members—Sir Archibald Geikie and Prof. E. Ray Lankester.

NOTES.

The following candidates selected by the council of the Royal Society were duly elected at the meeting on Thursday last, May 5:—Dr. T. G. Brodie, Major S. G. Burrard, Prof. A. C. Dixon, Prof. J. J. Dobbie, Mr. T. H. Holland, Prof. C. J. Joly, Dr. Hugh Marshall, Mr. Edward Meyrick, Dr. Alexander Muirhead, Dr. G. H. F. Nuttall, Mr. A. E. Shipley, Prof. M. W. Travers, Mr. Harold Wager, Mr. G. T. Walker, and Prof. W. W. Watts.

An influential committee has been formed for the purpose of striking a medal in honour of the memory of the late Prof. Cornu. The committee includes many members, foreign associates and correspondants of the Institute of France, as well as other leaders in the scientific world. The medal will be in bronze, silver bronze and silver, and the price will be 15 francs, 20 francs, and 50 francs respectively. Subscribers for the medal are invited to send their subscriptions to M. E. A. Martel, 8 rue Ménars, 2e Arrondissement, Paris.

At its meeting on Monday, May 9, the Academy of Sciences of Paris elected Prof. Barrois, of Lille, to fill the vacancy left in the section of mineralogy by the death of the illustrious Fouqué. This recognition of the claims of one of the most distinguished geologists of the present day will be welcomed far and wide, and nowhere more warmly than in the British Isles, where M. Barrois has many attached personal friends, and where he has himself done so much to illustrate the geology of this country.

As was generally expected, Prof. Rothpletz has been appointed to the chair of geology in the university at Munich and to the directorship of the State geological collections—the posts left vacant by the death of the lamented K. von Zittel. He has long been connected with the university, and has gained a wide reputation as an accomplished field geologist and a good palæontologist. His researches into the tectonics of the Alps have attracted much attention in this country, where he has many personal friends, and where he has made many geological excursions.

At a meeting of the U.S. National Academy of Sciences on April 21, Sir William Ramsay, K.C.B., was elected a foreign associate of the academy.

A Reuter message from Cape Town reports the arrival there of the steam yacht *Scotia*—the vessel in which the Scottish Antarctic Expedition sailed.

The death is announced of Mr. Eli Sowerbutts, who for the last twenty years had acted as secretary of the Manchester Geographical Society, which he was largely instrumental in founding. Mr. Sowerbutts was in his seventieth year.

Prof. Émile Bourquelot, of Paris, Sir Henry Littlejohn, and Dr. J. Wilson Swan, F.R.S., have been elected honorary members of the Pharmaceutical Society of Great Britain. The following have been elected corresponding members of the society:—Prof. E. Perrot, Paris; Prof. Heinrich Beckurts, Brunswick; Prof. Carl Hartwich, Zürich; Mr. S. T. Dunn, of the Hong Kong Botanical Gardens; and Dr. G. W. Parker, British Guiana.

The following have been elected honorary members of the Royal Institution:—Prof. E. H. Amagat, Prof. L. P. Cailletet, Prof. J. M. Crafts, Prof. H. A. Lorentz, Prof. E. W. Morley, Prof. E. C. Pickering, Prof. and Madame Curie, Prof. H. L. Le Chatelier, Prof. G. Lippmann, Prof. J. W. Bruhl, Prof. G. H. Quincke, Prof. E. Fischer, Prof. F. W. G. Kohlrausch, Prof. H. Landolt, Prof. L. Boltzmann, Dr. H. Kamerlingh Onnes, Dr. G. Lunge, Prof. P. T. Cleve and Prof. P. Zeemann.

Prof. van 't Hoff offers through the medium of the *Zeitschrift für physikalische Chemie* a prize of 60*l.* for the best and most complete synopsis of the literature of catalytic phenomena. Competitors are required to send in their papers before June 30, 1905, to the editors of the *Zeitschrift*, 2 Linnéstrasse, Leipzig, and the judges are Profs. van 't Hoff, Arrhenius and Ostwald.

An international congress on philosophy has been arranged to take place at Geneva from September 4 to 8 under M. Ernest Naville as honorary president and Prof. Gourd as acting president. The languages used will be English, French, German and Italian. The congress will be divided into five sections, dealing with history of philosophy, general philosophy and psychology, applied philosophy, philosophy of the sciences, and history of science. The secretary is Dr. Ed. Claparède, 11 Champel, Geneva.

The British Fire Prevention Committee offers a gold medal and a purse of 20*l.* for the best fable for children calculated to serve as a warning against the danger of

playing with matches or fire. Two silver and four bronze medals will also be given as additional awards for meritorious essays. The conditions can be obtained at the committee's offices, 1 Waterloo Place, London, S.W., upon application by letter, enclosing a stamped addressed envelope.

FOLLOWING the example of some other counties, a society has been formed for the photographic record and survey of Kent. The society is promoted by the South-Eastern Union of Scientific Societies, and its objects are "to make and preserve by permanent photographic prints, records of the present condition of objects of archæological, historical, or scientific interest · the geology, fauna, and flora of Kent; the customs and costumes of its people, notable events, and portraits of its prominent men and women." Good promise of support has already been received, and a successful first exhibition in June seems assured, but further help is desired. The organising secretary (*pro tem.*) is Mr. H. Snowden Ward, Hadlow, Kent.

A CORRESPONDENT of the *Times* directs attention to some of the geographical work done by the late Admiral Makaroff. In the early eighties of last century, Makaroff wrote a brochure of 147 pages, with nine charts, on the interchange of the waters of the Black Sea and Mediterranean, which was published by the Russian Academy of Sciences and awarded a full premium. On his return from his voyage in the *Vitiaz* in 1893 he wrote a report of his observations—848 pages and 33 charts. The report was likewise published and awarded a full premium by the Russian Academy. In 1901 he published an account of his ice-breaking steamer the *Yermak* and her work under the title of "The *Yermak* in the Ice."

WE are not concerned in these columns with the cause or course of the war between Japan and Russia, but it is impossible to read of the remarkable achievements of the Japanese without remembering that they owe their success to the encouragement of education and science. A writer in the *Daily Graphic* points out that while probably 95 per cent. of the Russian soldiers are illiterate, not more than 5 per cent. of the Japanese are illiterate, and he attributes the Japanese successes to their intelligence and initiative. It does not seem possible for the Russian soldiers to be placed in dispersed positions to think and act for themselves. "As for the officers," the writer continues, "where is genius to come from? The broad, liberal-minded men have been sent to Siberia, and all who have shown the characteristic mark of leadership in its contempt for bureaucracy have set a seal on their careers." Whatever may be said about Russia, it is certain that Japan is now furnishing the world with an example of "the influence of brain-power on history." Last September Sir Norman Lockyer referred in his British Association address to "the intellectual effort made by Japan, not after a war, but to prepare for one." Recent events have shown that the nation which endows universities and encourages science is making the best possible provision for military or naval conflict as well as for industrial competition.

IN the death of Dr. Charles Ricketts, at the advanced age of eighty-six, geological science has lost an ardent local worker, who practised as a physician for many years at Birkenhead, and devoted his leisure to the study of geology, more especially in Cheshire and Lancashire. He was twice president of the Liverpool Geological Society, and most of his geological papers were published in the *Proceedings* of that society. An interesting article, which he communicated in 1883 to the *Geological Magazine*, was on the influence of accumulation and denudation in causing oscillation of the earth's crust; in this he embodied deductions made and published by him as early as 1865. Dr. Ricketts was for many years a regular attendant at the meetings of the British Association.

THE fossil foot-prints of the Jura-Trias of North America form the subject of a memoir by Dr. R. S. Lull (*Mem.* Boston Soc. Nat. Hist., vol. v., No. 11, April). Two groups of foot-prints have been found impressed on the ancient shales and sandstones, the one bipedal and the other of quadrupedal gait. Both groups are considered to belong to dinosaurs. These are the only vertebrates the gait of which when erect could have been a true walk or run with alternating steps, which without exception the bipedal tracks show, there being no instance of the record of a jumping form. Of the truly quadrupedal forms, those referred to Batrachopus may have belonged to a true dinosaur which had retained, among other primitive characters, the ancestral quadrupedal gait. The mode of progression was a true walk like that of a mammal, and not the crawl of modern reptiles.

THE Geological Survey has issued a colour-printed drift map of the area around London, on the scale of one inch to a mile, in four sheets, price 1*s.* 6*d.* each. The execution of this map has been carried out at the Ordnance Survey Office, and the colour printing is in all respects excellent. The map is intended to replace the old hand-coloured geological map of London and its environs, the cost of which was 30*s.* This reduction in price will be a boon to all interested in the geology of the metropolitan district. The new map does not cover quite so large an area as the old one, but it extends on the north to Watford, Enfield, High Beech and Kelvedon Hatch; on the east to Brentwood, Upminster, West Thurrock, Greenhithe and Kingsdown; on the south to Shoreham, Croydon, Sutton, Ewell and Byfleet; and on the west to Chertsey, Staines, Uxbridge and Rickmansworth. The results of a recent six-inch survey of the Thames valley deposits have been incorporated on the new map, the brickearths not having previously been accurately defined.

WE have received from the president of the International Aëronautical Committee a summary of the balloon and kite ascents made in various countries during the months of January to March. Among the highest altitudes reached we may mention the ascents from Paris, 15,000 metres; Pavia, 13,000 metres; Strassburg, 15,500 metres; Munich, 13,000 metres; Pavlovsk, 18,960 metres; Guadalajara, 13,220 metres; and Zürich, 14,430 metres. Mr. Dines's kite at Oxshott attained an altitude of 1100 metres. The meteorological results are reserved for future discussion; unfortunately several of the records have not been recovered.

THE daily weather report issued by the Meteorological Office on May 4 contains a small inset chart showing the total amount of rainfall recorded in the United Kingdom in the seventeen weeks ended April 30, together with the percentage of the average amount. In all districts excepting the north-east of England the fall has been in excess of the average. In the extreme north (Scotland) the amount is 121 per cent. of the average, and in the extreme south (Channel Islands) 144 per cent.; in the north-west of England it is 122 per cent. In Ireland the amount is 126 per cent. in the north and 116 per cent. in the south. In the east and north-east of England the fall has been practically normal.

A letter received from Mr. W. Comery, Llandilo, Carmarthenshire, gives an account of variations noted in the parts of the flower of the primrose during the current year, and provides data for comparison with the observations recorded by Mr. T. G. Hill in the *Annals of Botany*, June, 1902. According to our correspondent, variation in the number of parts was confined to 4 and 6, except in the cases where one flower had 8 sepals, 7 petals, and 6 stamens, two were decamerous, and one was trimerous. The corolla showed the greatest amount of variation; of ninety-four irregular flowers, 79 per cent. showed reduction in the number of petals, and the proportion of long styled to short styled was nearly 7 : 3, but of twenty flowers showing increase in the number of petals the proportion was exactly inverse.

An extensive series of observations on the number of fungus spores present in the air has been made by Mr. K. Saito (*Journ.* of the College of Science, Imp. Univ., Tokyo, Japan, xviii., art. 5). The observations were made in the Botanic Garden, streets, operating theatre of the hospital, and certain rooms. It was found that the spores were more numerous in warm and damp than in cold and dry weather, and that rain and snow diminished while a strong wind increased their number. The commonest species were *Cladosporium herbarum, Penicillium glaucum* and *Epicoccum purpurascens*. Three new species are described. The article is illustrated with charts and a number of figures; the latter would prove useful in the identification of the species of fungi that might be met with in laboratories, &c.

With the exception of one on field-practice with the aneroid, and a second on the moths of the family Geometridæ, the articles in the second part of vol. xvi. of the *Proceedings* of the Royal Society of Victoria are devoted to palæontological and geological subjects. Three of these are communicated by Mr. F. Chapman, who describes Jurassic Foraminifera and Ostracoda from W. Australia, Palæozoic and Mesozoic invertebrates from W. Australia and Queensland, and various Palæozoic fossils from Victoria. Mr. C. M. Maplestone discusses the fossil Selenariidæ of the last named colony.

According to the report for last year, the hatching of sea-fish at Piel has been most successful, nearly 15,000,000 fry having been obtained from about 17,000,000 eggs. This gives a total loss of rather less than 11 per cent. for the whole operations, which is almost certainly vastly below what occurs in nature. It is incidentally mentioned by Prof. Herdman that plaice in the closed Scotch waters have been found to run much larger than on the over-fished Lancashire coast. The feature of the report under consideration—namely, that on the Lancashire Sea-Fisheries Laboratory—is, however, undoubtedly Dr. J. H. Ashworth's elaborate and beautifully illustrated account of the life-history and structure of the lug-worm, which is the result of several years hard and careful work.

Among recent mathematical papers published in the United States may be noticed the following:—L. E. Dickson, determination of all the subgroups of the known simple group of order 25920 (*Trans.* Amer. Math. Soc., v. p. 126); C. N. Haskins, on the invariants of quadratic differential forms (*ibid.*, p. 167); C. Arzelà, note on a series of analytic functions (*Ann. of Math.* (2), v., p. 51); A. G. Greenhill, the mathematical theory of the top (*ibid.*, p. 67); H. A. Converse, on a system of hypocycloids of class three (p. 105); E. B. Wilson, projective and metric geometry (p. 145); W. F. Osgood, on a gap in the ordinary presentation of Weierstrass's theory of functions (Amer. Math. Soc. *Bull.*, March). The first number of vol. xxvi. of the *American Journal of Mathematics* is accompanied by a portrait of Prof. Noether; its principal contents relate to the theory of groups, but there is a paper by Prof. Bromwich on caustics which is of a less abstract character.

Messrs. J. and A. Churchill have published a sixth edition of "A Manual of Dental Anatomy: Human and Comparative," by Mr. Charles S. Tomes, F.R.S.

Messrs. Iliffe and Sons, Ltd., have published sixth editions of "Photography for All," by Mr. W. Jerome Harrison, and of "Practical Enlarging," by Mr. John A. Hodges. The price of each book is 1s. net.

A sixth edition of "A Treatise on Hydromechanics. Part i. Hydrostatics," by Dr. W. H. Besant, F.R.S., and Mr. A. S. Ramsey, has been published by Messrs. George Bell and Sons. For the present edition the text has been carefully revised, and considerable additions have been made to some sections of the book.

A second edition of Mr. T. W. Cowan's "The Honey Bee: its Natural History, Anatomy, and Physiology," has been published by Messrs. Houlston and Sons. The first edition was reviewed at length in our issue of April 23, 1891 (vol. xliii. p. 578). It is consequently only necessary to add that the present edition has been revised and corrected.

The delegates of the Clarendon Press have taken over the series of geographical memoirs known as "The Regions of the World," which is under the general editorship of Mr. H. J. Mackinder, and in future this series will be published by Mr. Henry Frowde. Two new volumes will be issued this year—"North America," by Prof. Israel Russell, of the University of Michigan, at the end of this month, and "India," by Sir Thomas Holdich, K.C.I.E., in the early autumn. It is hoped that "The Far East," by Mr. Archibald Little, will soon be in the press.

In the March number of the *Journal of Physical Chemistry*, Messrs. H. E. Patten and W. R. Mott describe experiments on the electrolytic deposition of metallic lithium from solutions of lithium chloride in ethyl, propyl, butyl and amyl alcohols. By the use of organic solvents the electrolytic separation of metals not obtainable from aqueous solutions seems possible in many cases.

In the April number of the *American Chemical Journal* Messrs. H. C. Jones and F. H. Getman discuss the nature of concentrated solutions of electrolytes. As the result of an extended investigation of the freezing points, boiling points and conductivities of such solutions, the authors arrive at the conclusion that combination takes place between the solvent and the dissolved substance. As a consequence of this, such solutions are really more concentrated than they would appear to be from the amount of dissolved substance present in them, and many of the discrepancies exhibited by concentrated solutions are explainable.

The April number of the *New Philosophy*, published by the Swedenborg Scientific Association, contains some interesting notes in reference to Swedenborg's work in chemistry. Whilst Prof. van 't Hoff acknowledges it as the first work which anticipated the modern science of stereochemistry, others regard Swedenborg's work as having had absolutely no influence upon chemical thought or discovery. Prof. F. W. Clarke recently described it as "the

prototype of a class of speculative treatment, considerable in number, some of them recent, and all of them futile."

IN the current number of the *Zeitschrift für anorganische Chemie*, Prof. B. Brauner describes the preparation and properties of acid sulphates of the rare earths. The cerium salt has the formula $Ce_2(SO_4)_3.3H_2SO_4$, and salts of the same type have also been obtained for lanthanum, praseodymium, neodymium, samarium and yttrium. These acid sulphates are only incompletely converted into the normal salts at high temperatures, and the author's opinion is that all atomic weight determinations of the rare earth metals, in which the sulphates obtained synthetically have been employed, are on this account inaccurate.

IN the March number of the *Physical Review*, Mr. T. E. Doubt describes some experiments dealing with the effect of the intensity on the velocity of light. The results of these experiments justify the conclusion that for light travelling in air a change in intensity in the ratio of 1 to 290,000 does not alter its velocity by as much as 57 centimetres per second. In the case of water, a change in intensity in the ratio of 1 to 43,000 does not alter the velocity by as much as 80 centimetres per second, that is, by 1 part in 1000 million parts.

THE additions to the Zoological Society's Gardens during the past week include a Pig-tailed Monkey (*Macacus nemestrinus*) from India, presented by Mrs. Mackenzie Fraser; a Smooth-headed Capuchin (*Cebus monachus*) from South-east Brazil, presented by Mr. Arthur Collins; a Ruffed Lemur (*Lemur varius*) from Madagascar, presented by Lady Constance Stewart Richardson; a Pigmy Hog (*Porcula salviana*) from Bhotan, presented by Mr. D. H. Felce; two Markhoors (*Capra megaceros*) from North-east India, two Punjaub Wild Sheep (*Ovis cycloceros*) from North-west India, presented by Colonel Deane; three Chinchillas (*Chinchilla lanigera*) from Chili, presented by Mr. Andres Ker; two Coypu Rats (*Myopotamus coypus*) from South America, presented by Mr. H. L. Horsfall; two Ring-tailed Pigeons (*Columba caribbaea*) from Jamaica, presented by Mr. D. Seth-Smith; two Spur-winged Geese (*Plectropterus gambensis*) from West Africa, presented by Mr. J. Lemberg; two Nutmeg Fruit Pigeons (*Myristicivora bicolor*) from Moluccas, two Imperial Nicobar Fruit Pigeons (*Carpophaga insularis*) from the Nicobar Islands, four Andaman Teal (*Nettion albigulare*), three Andaman Banded Crakes (*Rallina canningi*), six Great-billed Andaman Parrakeets (*Palaeornis magnirostris*) from the Andaman Islands, presented by the Government of India; an Exanthematic Monitor (*Varanus exanthematicus*) from West Africa, presented by Mr. Dayrell; a Rufescent Snake (*Leptodira hotambioea*) from South Africa, presented by Mr. B. McMillan; an Allen's Bassaricyon (*Bassaricyon alleni*), six Red and Black Snakes (*Erythrolampus venustissimus*) from South America, an Australian Cassowary (*Casuarius australis*), a Gould's Monitor (*Varanus gouldi*), a Lace Monitor (*Varanus varius*), a Blue-tongued Lizard (*Tiliqua scincoides*), a Derbian Wallaby (*Macropus derbianus*) from Australia, a Sooty Phalanger (*Trichosurus fuliginosus*) from Tasmania, two Australian Barn Owls (*Strix delicatula*) from Australia, an Orton's Guan (*Penelope ortoni*) from Ecuador, a Gold-crested Mynah (*Ampeliceps coronatus*) from India, a Sarus Crane (*Grus antigone*) from Northern India, five Lineated Sand Skinks (*Chalcides lineatus*), South European; four Californian Newts (*Molge torosa*) from California, deposited; a Black Ape (*Cynopithecus niger*) from the Celebes, ten Crested Pigeons (*Ocyphaps lophotes*) from Australia, purchased.

OUR ASTRONOMICAL COLUMN.

SOLAR WORK AT THE SMITHSONIAN ASTROPHYSICAL OBSERVATORY.—Incorporated in the annual report of the Smithsonian Institution, for the twelve months ending June 30, 1903, is a report of the work performed in the Astrophysical Observatory, during that period, by Mr. C. G. Abbot who is in charge.

A new horizontal telescope of 20 inches aperture and 140 feet focal length, fed by a novel form of two-mirror cœlostat, and fitted with an apparatus for thoroughly churning the air inside the tube during the observations, has been mounted for the bolographic study of the solar image, and especially sun-spot energy spectra and the absorption of the solar envelope.

The most notable result of the study of the atmospheric absorption during the above named period was the decreased transparency of the atmosphere, at Washington, for all wave-lengths, but especially for the violet and ultraviolet radiations. Other results showed that this result was not caused by an excess of moisture in the atmosphere. Several plates which are included in the report show a diagrammatic view of the new instrument, typical "bolographic energy" and "atmospheric transparency" curves, a curve showing the distribution of radiation in the normal solar spectrum outside the earth's atmosphere, and a photograph of the large cœlostat with the second mirror.

METEOR RADIANTS OBSERVED AT ATHENS.—A communication from Prof. D. Eginitis to No. 3941 of the *Astronomische Nachrichten* gives a list of the radiants observed at Athens during 1902. Two radiants not given in Denning's "General Catalogue" were recorded in June and July, respectively, as follows:—

June 27, 10h. 58m. – 12h. 16m. (Athens M.T.) $\alpha = 230°, \delta = +73°$
July 29, 10h. 40m. – 11h. 27m. („) $\alpha = 85°, \delta = +85°$

Several of the radiants obtained from the observations at Athens differ considerably both in time and position from their respective values given in the above named catalogue.

The observed radiant for the Perseid shower spreads over a large area, and the principal centre, situated near to η Persei, alters its position considerably. The Perseids from the region near to α Persei were generally red and bright, whilst those from near η Persei were fainter and of a reddish-yellow colour.

SOLAR FACULÆ AND PROMINENCE VARIATIONS.—In a paper communicated to No. 3, vol. xxxiii., of the *Memorie della Società degli Spettroscopisti Italiani*, Prof. Mascari analyses the latitude and frequency variations of faculæ, as observed at Catania, in a manner similar to that recently used by Sir Norman and Dr. Lockyer, whose results he corroborates, for the spots and prominences.

After discussing the data obtained from his observations in a series of tables and curves, he arrives at the following general conclusions:—(1) The zone of maximum activity of the groups of faculæ lies between the mean latitude $\pm 45°$ and the equator, and pursues a movement parallel to, and coincident with, that of the spots, but the inverse of that of the prominences. (2) The faculæ beyond the principal maximum, in the equatorial region of each hemisphere, are not represented in the polar regions. (3) The centre of maximum activity of the prominences occurs generally in the region of minor activity of the faculæ.

MAGNITUDE OBSERVATIONS OF NOVA PERSEI.—In No. 3941 of the *Astronomische Nachrichten*, Father Hagen, S.J., gives a list of the magnitudes of Nova Persei as observed at Georgetown (U.S.A.) with a 12-inch refractor, from June 19, 1901, to April 18, 1903. The magnitude on the latter date, from an observation made when the Nova was near the horizon, was 11·05.

A similar list of magnitude observations, made at Kalocsa by Father M. Esch, S.J., during the period July 8, 1901, to March 22, 1902, is given in No. 3943 of the same journal.

COMET 1904 *a*.—Numerous observations of this comet are recorded in Nos. 3943–4 of the *Astronomische Nachrichten*. Dr. Hartwig, observing at Bamberg on April 17, recorded the total magnitude as 9·0, and the magnitude of the nucleus alone as 10·0. The comet had a broad divided tail 4′ long, the mean position angle of which was 211°; the coma was 1′·5 in diameter.

The following is a continuation of the ephemeris published by Herr M. Ebell:—

Ephemeris 12h. M.T. Berlin.

1904		α		δ
		h. m. s.		° ′
May 22	...	14 37 10	...	+57 57
„ 26	...	14 20 29	...	+58 1
„ 30	...	14 6 26	...	+57 44

An error, due to the ambiguity of a necessarily brief telegram, was contained in a previous paragraph concerning this object. This comet is a new one discovered by Mr. Brooks, and *not* the Brooks's comet of 1896 returned.

Orbit of the Spectroscopic Binary ι Pegasi.—No. 53 of the Lick Observatory *Bulletins* is devoted to a detailed discussion of the definitive orbit of ι Pegasi by Dr. Heber D. Curtis. The elements obtained have been derived from measurements of forty-three plates taken during the period October 7, 1897, and December 1, 1903, inclusive.

Three sets of elements, each one giving a nearer approximation to the observed values than the one preceding it, were evolved, and the derivation of each set is given in full detail. The final set gives a velocity of -4.12 ± 0.11 km., and a period of 10.21312 ± 0.00006 days. Owing to the small eccentricity of the orbit, viz. 0.0085, the epoch of periastron is not very certain, but is given as 1899 June 14.966 ± 0.352 days.

IRON AND STEEL INSTITUTE.

The annual meeting of the Iron and Steel Institute was held at the house of the Institution of Civil Engineers on May 5 and 6 under the presidency of Mr. Andrew Carnegie. The report of the council, read by the secretary, Mr. Bennett H. Brough, showed that the institute continues to make satisfactory progress. The president then presented the Bessemer gold medal to Mr. R. A. Hadfield (Sheffield). The announcement was made that awards of 100*l.* from the Carnegie research fund had been made to John Dixon Brunton (Musselburgh), Dr. H. C. H. Carpenter (National Physical Laboratory), E. G. L. Roberts and E. A. Wraight conjointly (London), Frank Rogers (Cambridge), and Walter Rosenhain (Birmingham), and a renewed award of 50*l.* to O. Boudouard (Paris). The Andrew Carnegie gold medal for research was awarded to Pierre Breuil (Paris), and a special medal to Percy Longmuir (Sheffield).

The first paper read was by Mr. A. Dupré and Captain M. B. Lloyd, H.M. Inspector of Explosives, on explosions produced by ferrosilicon at Liverpool on January 12 and 21. The explosion was most probably caused by water having got into the interior of the drums containing the ferrosilicon; the gas evolved formed, with the air in the drums, an easily ignited explosive mixture, which was fired by the heat produced by the friction of the hard lumps against each other when the drums were moved about, or possibly by the spontaneous ignition of some phosphuretted hydrogen contained in a pocket in the material, and liberated suddenly by the breaking of a lump on the drum being moved. Although the accidents were not attended by very grave results, it is important that all those who have to handle ferrosilicon should be alive to the possible dangers attaching to it, and by keeping it in a dry and thoroughly well ventilated place prevent the accumulation of inflammable gas as far as possible.

Prof. H. Louis (Newcastle-on-Tyne) then read a paper on the manufacture of pig iron from briquettes at Herräng, Sweden. The mining and smelting of the ore present many novel features. Briefly the scheme of operations is as follows:—The ore as mined is conveyed from the various mines by aërial wire rope-ways to the crushing works, where it is broken and crushed wet; the pulp runs to the magnetic concentrators, which take out the magnetite; the latter is conveyed by a small aërial rope-way to the briquetting house, where it is stamped into briquettes, which pass next through the briquetting furnace, in which they are burnt; they are then hoisted up to the top of a pair of charcoal furnaces, where they are smelted for high-class pig iron; the waste gases from the blast furnace fire the briquetting furnaces, and supply gas-engines which furnish the blast and also drive the dynamos of a central electrical station, from which power is conveyed to the concentrating works, as well as to the various mines for hoisting, pumping, &c. Several of the principles embodied appear destined to play an important part in the metallurgy of iron in the near future.

Mr. Cosmo Johns (Sheffield) read a paper on the production and thermal treatment of steel in large masses. He indicated some of the conditions which differentiate works' practice from laboratory research.

An interesting feature of the meeting was an exhibition of pyrometers. At the Barrow meeting of the Iron and Steel Institute, the suggestion was made that, in view of the growing importance of pyrometers to the steel industry, arrangements should be made to enable members to see the actual working of different pyrometers in order to enable them to form their own opinions of the relative merits of the appliances available for metallurgical purposes. The council readily adopted this suggestion, and appointed a committee, consisting of Mr. R. A. Hadfield (vice-president), Mr. J. E. Stead (member of council), and Mr. B. H. Brough (secretary), to make the necessary arrangements for the exhibition. Invitations were sent to all the leading makers to exhibit pyrometers and to furnish brief descriptions of them. The descriptions occupied a pamphlet of sixty-two pages, and dealt with the following types:—(1) Baird and Tatlock pyrometer, (2) Bristol's recording air pyrometer, (3) Callendar and Griffith resistance pyrometer, (4) Le Chatelier pyrometer, (5) Mesuré and Nouel optical pyrometer, (6) Roberts-Austen recording pyrometer, (7) Rosenhain and Chalmers pyrometer, (8) Siemens electrical pyrometer, (9) Siemens water pyrometer, (10) Uehling pneumatic pyrometer with Steinbart automatic recorder, (11) Wanner optical pyrometer, (12) Wiborgh's thermophone, (13) Zaubitz pyrometer. In conclusion, a list of patents relating to pyrometry, compiled by Mr. H. G. Graves, and a full bibliography of the subject were given.

Mr. C. Lowthian Bell (Middlesbrough) read an important paper on the manufacture of coke in the Hüssener oven at the Clarence Iron Works, and its value in the blast furnace. The results show that with this oven a coke can be made giving as good results in the furnace as that made in the old beehive oven.

Dr. H. C. H. Carpenter and Mr. B. F. E. Keeling submitted a paper on the range of solidification and the critical ranges of iron-carbon alloys. The research, which was carried out at the National Physical Laboratory, confirms, broadly speaking, the accuracy of Bakhuis-Roozeboom's diagram. Further, the results indicate that the diagram will be amplified in certain parts when the equilibrium between the various phases has been more fully studied, viz. on account of (1) the small thermal change at about 790° for alloys with carbon content 0.8–4.5; (2) the slow thermal change at about 600° found over the whole range of alloys; (3) the evolutions of heat at about 900° found in alloys with carbon content of 3.87 and 4.50.

Mr. H. C. Boynton (Harvard University) submitted a paper on troostite, in which he gave the results of experiments made with the object of furnishing facts in regard to the identity of this constituent of steel, which, although mentioned by prominent metallurgists, has not apparently been generally accepted or understood.

A paper on the synthesis of Bessemer steel was presented by Mr. F. J. R. Carulla (Derby), in which he gave particulars of the manufacture of steel rails in 1874 by the acid process of a quality so uniform as to leave nothing to be desired. He urges that modern requirements should be equally well fulfilled, and that endeavours should be made to introduce improvements in the Bessemer process so as to prevent its being altogether put aside in favour of the open-hearth process.

Mr. W. J. Foster (Darlaston) submitted a paper on the thermal efficiency of the blast furnace, in which he gave the results obtained with the furnace at Darlaston 72½ feet high, in which the materials smelted are chiefly silicates of iron.

Mr. W. Rosenhain (Birmingham) contributed a paper on the plastic yielding of iron and steel. He described some new observations explaining the curved slip-bands in iron and mild steel. This curvature is shown to be probably due to a multitude of minute steps, and a reason is thus

suggested why this stepping should be so marked a feature in iron, while it is so comparatively rare in certain other metals. This reason is that the ferrite crystals in ordinary iron and steel are formed by crystallisation from a solid solution, while the ordinary crystals of lead, for instance, are formed by crystallisation from a true liquid. The truly crystalline character of slip-bands is further demonstrated in a novel manner by the observation of slip-bands in iron following and revealing the gliding planes of twin crystals. Finally, the view has been advanced that the strength of inter-crystalline cohesion in pure metals and certain forms of alloys is due to the interlocking of the skeleton arms which the crystals develop during their first formation. According to this view, the inter-crystalline boundaries take the form of regions of mixed orientation, and certain consequences are to be deduced from this consideration. It is argued that, since a region of mixed orientation must offer greater resistance to slip than a region of uniform orientation, the inter-crystalline boundaries form a network of cells upon which the true resistance of the metal depends. Plastic deformation sets in when these cell-walls begin to give way; in doing so they carry with them the less resisting masses of the crystalline grains. In this way the observed relation between slip-bands and inter-crystalline boundaries is explained. Observations of a frequent doubling of the inter-crystalline boundaries between ferrite grains in pure iron and the "bordered boundaries" and "spines" in strained metal are adduced as further evidence in support of this view of the structure of inter-crystalline boundaries.

Mr. B. H. Thwaite (London) contributed a paper on the use of steel in American lofty-building construction. During the past five years some 200,000 tons of steel have been annually consumed in steel frame construction in the United States.

Mr. P. Breuil (Paris) submitted a report on the work carried out by him as a Carnegie research scholar. It dealt with the relations between the effects of stresses slowly applied and of stresses suddenly applied in the case of iron and steel. He showed that the tests made with nicked bars, a widely extending practice in France, were just like those made with plain bars, but much less clear and precise. The nicking of test bars simply introduces a further complication.

Mr. P. Longmuir (Sheffield) submitted a report on his research, as a Carnegie scholar, on the influence of varying casting temperature on the properties of steel and iron castings. With mild steels the influence of casting temperature does not appear to show on the tensile properties. Low casting temperatures, however, appear to induce a type of brittleness not evidenced in the tensile test, but shown in the working life of the metal. It is possible that many of the mysterious fractures of steel, which has previously passed a rigorous inspection, may be traced to the original ingot having been cast at too high or too low a temperature.

THE SOUTH AFRICAN ASSOCIATION.

THE second annual meeting of the South African Association for the Advancement of Science was held at Johannesburg during the week commencing April 4. At the opening meeting Lord Milner presided, and Sir Charles Metcalfe delivered his presidential address, which, in addition to a review of the scientific advances during the preceding year, contained a number of comments on some of the causes which have effected the great advances in scientific knowledge in recent years.

Portions of the address appeared in the Johannesburg *Star*, and we have selected from them a few extracts of scientific interest. The only address which has reached us is one given by Mr. E. B. Sargant on "The Education of Examiners," and an abridgement of this will probably appear in our next number. For the subjoined abstracts of other addresses and papers we are indebted to the Johannesburg *Star*.

Presidential Address.

Referring to diseases of stock, Sir Charles Metcalfe said:—In Rhodesia, Dr. Koch has been spending the whole year in laborious and patient investigation of the African coast fever among cattle, and he has now reported that he has found that it is caused by a blood parasite which can be readily identified by a demonstration of the specific organism, that it is different from Texas fever, or so-called red-water, that it is not transferable directly, that sick animals can be stabled with healthy ones without communicating the disease, and that the disease can only be spread by ticks. Further, that the blood of animals which have recovered and become immune is not free from parasites, and that the disease therefore can be produced in healthy animals by the transfer of parasites from salted animals by means of ticks, and though fencing, dipping and spraying are beneficial, yet as they have only a temporary value, Dr. Koch recommends that these precautions should be supplemented by inoculation with the blood of animals that have recovered whenever disease breaks out in the vicinity.

Turning to another subject, the president continued:—the geodetic survey of Africa, the inception and continuation of which owe so much to our past president, Sir David Gill, is being proceeded with both in the Transvaal and in northern Rhodesia beyond the Zambezi. It is intended to extend it northwards more or less, probably along the route of the Cape to Cairo railway, that projected line which to many appears, perhaps, to belong to the things of dreamland. You, however, who know South Africa well will agree with me that in this country it has generally been found that the sanguine man has ever been the truest prophet. When this geodetic survey has been connected up with that of Europe, which has now been extended as far north as Spitsbergen, we shall have an arc from that point to Cape Town—the longest arc that is possible to us on this globe. All civilised nations have found the advantage of having proper and accurate maps, and it is hoped that a useful work may now be undertaken in South Africa by a system of secondary triangulation. This work will necessarily take many years to complete; every year, however, the recorded results will be of value, as they will enable correct maps to be compiled showing the topography and main features of the country and the situation of the larger farms, of the most important and more populated districts in the first place, and then of the more remote parts of the country.

Introducing the subject of anthropological research, the president remarked that Prof. Haddon, when president of the Anthropological Institute, expressed himself strongly on the urgency of anthropological research. "In view," he said, "of the decrease of the native races by the advance of civilisation and the changes in the habits of the survivors, no time is to be lost in the acquisition of scientific knowledge by direct observations." There is wide scope and much opportunity in South Africa for such research, though Sir Charles Metcalfe said "the argument about their decrease and the use of the word 'survivors' read strangely to us, who see the native races not decreasing but happily increasing in numbers as well as in material prosperity."

Later in his address Sir Charles Metcalfe directed attention to the fact that for research into the causes and preventives of disease, both in human beings and in animals, there is a great field in South Africa. Continuing, he remarked, "The various Governments here have shown commendable vigour in dealing with those terrible scourges, rinderpest, plague, and red-water, and have acted in a spirit of the truest economy by securing the services of the most able men of science of the day in their investigation. When England was ravaged by rinderpest, no remedy was discovered; the animals affected were simply destroyed at a cost of some nine millions of money. It was left for South Africa, at a later date, when knowledge was more advanced by the admirable work of the scientific investigators engaged on that task, to be the first to discover a preventive for that disease, a fact of which this country may well be proud. I have mentioned Dr. Koch's great work in the investigation of cattle fever in Rhodesia. He has also at the same time undertaken researches into some others of the diseases affecting animals in South Africa, amongst them that most familiar but terrible disease which we call horse-sickness, a disease by which the country loses not only many thousands of pounds annually by the deaths of valuable animals, but also the large amount

that otherwise might be realised by the breeding of horses and mules. I understand that Dr. Koch is sanguine as to the result of his researches. Time alone will show whether his efforts or those of Dr. Edington and other labourers in this field have given us the much-to-be-wished-for certainty of rendering horses and mules immune from this disease. Work is being carried on in the investigation of the other manifold sicknesses to which animals are liable in South Africa, but 'science is slow,' and much more time and patient research are necessary before we can arrive at what we look forward to—a period when we shall no longer be helpless and at the mercy of these devastating pests."

Papers read before Section A.

The genesis of soils, with special reference to the Transvaal, by Mr. A. F. Crosse. The author pointed out that the bulk of the parent rocks are of small potential value as soil formers. Illustrative of these deductions, he instanced the well known poverty of granite soils, and in contrast gave as an example the fertile soils of the Marico and Rustenburg districts. In these districts, situated around the edge of the granite, are numerous intrusions of basic rock, of high agricultural potentialities—as a result, the soils formed therefrom are the richest in the country. Mr. Crosse is optimistic as regards the future of agriculture in the Transvaal. Given a fair proportion of the revenue obtained from the taxation of the industry devoted to the intelligent fostering of agriculture, he did not see why, with the aid of science, farming on a fairly large scale should not give a fair return to the agriculturist, and so maintain that most necessary class—the yeoman farmer.

The metallurgy of the Transvaal, by Mr. J. Williams, president of the section. The author said that the mining of gold, until very recently, had been conducted in a very primitive manner. The Plattner process, for a long time, was the only one which held the field, but it could only be used in conjunction with some method of concentration. It was, however, left to Mr. McArthur to show that cyanide could be used commercially for the extraction of gold. Mr. Williams then proceeded to give an outline of the modern process of extraction as used in the Transvaal.

Some practical observations on forestry, by Mr. D. S. Muldoon. The author gave a list of trees that grew well in the Transvaal, and were of high economic value. He also mentioned the advisability of planting trees along the railway lines; these trees would be of use in affording shelter to the locomotives, which could, therefore, maintain more steam, especially in high winds, and when the trees were full grown the railway would have its own supply of timber for sleepers, beams, &c. A knowledge of forestry should also be given in the State schools, and children encouraged to plant trees, shrubs, and plants around the waste places surrounding the school sites. The utility and value of trees indigenous to the country were also touched upon. The advisability of street tree-planting in the towns of the Transvaal was also pointed out, and the attention of the president was directed to the need for a Forestry Bill dealing with timber on Crown lands.

Duration and areas of heavy rainfalls, by Mr. D. C. Leitch. The author gave figures as found by observatories in England and America on the rates of rainfalls, quoted Prof. Talbot's formula, and gave some results obtained in the Transvaal. He quoted one instance where 4·86 inches of rain fell in one hour, whereas the heaviest rainfall in the British Isles does not exceed the rate of 1·8 inches per hour. The author mentioned that the recent Bloemfontein flood was said to be due to a rainfall of $2\frac{1}{4}$ inches over 14 square miles of catchment area.

Mr. G. A. Denny read a paper on diamond drilling and prospecting by drilling.

The prehistoric monuments of Rhodesia, by Mr. E. P. Mennell. The author discussed the question as to the origin of the larger of the various ruins which occurred in Rhodesia, depicting the possibility of the structures having been erected by indigenous tribes.

Nature-study in South Africa, by Mr. Sclater. The author pointed out the weakness of the type system of the study of biology. The love of nature should be fostered by the teacher taking children into the field. For example, in the case of birds, the child should be taught to note the times of migration, and inquire to what extent migrating birds nest in South Africa. They knew very little about the mammals of South Africa. They knew little about the life-history of frogs and toads. The habits of spiders opened up a large field for study. He urged that pupils should be encouraged to collect so as to form school museums.

The cyanide process from the standpoint of modern chemistry, by Dr. J. Moir. Dr. Moir described the solution, precipitation, &c., of gold on the line of the ionic theory, and showed that various reactions which had formerly been considered obscure could quite well be explained by it.

Some economic problems in metallurgy on the Witwatersrand, by Mr. Harry S. Denny. The author dealt with the salient features of metallurgical practice on the Witwatersrand from the point of preliminary breaking to the handling of slimes and sand residues.

The evolution of the treatment of by-products on the Witwatersrand, by Mr. M. Torrente. The author summarised the principal by-products produced in a mine as follows:—In connection with the battery: concentrates, black sands, sweepings, slags, pots, ashes, battery chips, and screenings. In connection with chlorination works: pots and ashes. In connection with cyanide works: concentrates, sands and slimes, slags, white slimes, Prussian blue, scrapings, sweepings, skimmings, dross, litharge, brick dust, test bottoms, sump sediments, ashes, crucibles and liners. The list is large, and if there is to be any profit, the cost of recovery must necessarily be less than 4*l.* a ton. Although, said the author, much has been attained, plenty of problems still await solution. On the Rand money is lavishly spent if there seems the remotest chance of effecting an improvement. The friendly rivalry, as well as the interchange of ideas and experiences, all help in the same way, and this is one of the most noticeable features of the scientific life of the Rand.

The chemical industry of the Transvaal: a forecast, by Mr. W. Cullen. The author remarked that on account of the gold industry being such a large factor in the prosperity of South Africa, they were sometimes inclined to overlook the possibilities of others. The chemical works and the dynamite industry managed to exist now with practically no protection, and this ought to make them look around. Proceeding, he outlined the existing chemical industries of the Transvaal the total making a very poor show. He included the cement works at Pretoria, which, he said, was now manufacturing an article equal to European brands. Looking ahead, he asserted that the term metallurgy, as used in the Transvaal, would soon have a much wider meaning than at present, and would embrace that of zinc, lead, copper, and possibly tin and iron. Foremost among the chemical imports was that of cyanide, and he was optimistic about the possibility of manufacturing it in the Transvaal at a profit. The plague, and the greater attention being paid to matters sanitary, had created a steady demand for chloride of lime, all the raw materials for which were to be found in the country. There would soon be a great demand for artificial manures, and here again nearly everything was at hand. Among other possible industries, he mentioned that of candles and oil from the shale which was abundant, alkali from by-products, glass, soap, alcoholic fermentation and distillation, when potatoes and mealies became cheaper, &c.

The contact process of sulphuric acid manufacture, by Mr. E. Weiskopf. Results of some further observations upon the rate of evaporation, by Mr. J. R. Sutton.

Papers read before Section B.

Biological and ethnological observations on a trip to the north-east Kalahari, by Dr. Schonland.

The geological features of the diamond mines in the Pretoria district, by Mr. Herbert Kynaston, director of the Geological Survey, and Mr. A. L. Hall. The authors, after describing briefly the area and situation of the Transvaal diamond fields, proceeded to give an account of the general geological structure of the district in which they occurred. The diamond pipes contributed a group situated on the high ground forming the watershed between the Elands and Pienaars Rivers, about 22 miles east of Pretoria. They have been intruded into the uppermost beds of the Pretoria series—a formation consisting of quartzites, shales, and diabase sheets, lying between the dolomite and the Waterberg sandstones—and are found to be surrounded partly by

quartzite and partly by intrusive sheets of diabase and felsite. Their situation is, in the authors' opinion, associated with lines of weakness which have been set up by the movements and dislocations which have affected the Pretoria series in the diamond field area. In the case of the Premier Mine, the pipe is almost entirely surrounded by a felsitic rock, which is intimately associated in places with a diabase. This diabase and felsite, in fact, pass gradually the one into the other, and form the lower and upper portions respectively of a large intrusive spot. The walls of the Premier pipe at lower levels, however, appear to consist of the quartzite which underlies this sheet.

Alien plants spontaneous in the Transvaal, by Mr. Joseph Burtt-Davy. The author dealt with the question, Where do our immigrant plants come from? An analysis shows that the regions where the immigrants are native are approximately as follows:—the Mediterranean region (*i.e.* the countries of south Europe, west Asia, and North Africa, immediately bordering the Mediterranean Sea), approximately 42 per cent.; tropical Asia, approximately 10 per cent.; tropical Africa, approximately 9 per cent.; tropical America, approximately 18 per cent.; northern Europe, approximately 7 per cent.; South Africa, approximately 6 per cent.; temperate North America, approximately 3 per cent.; Australia, approximately 3 per cent.; temperate South America, approximately 2 per cent.; Central Asia, approximately 1 per cent. The means by which plants migrate from country to country were then considered. The author said these fall under two heads:—(*a*) artificial means or by the agency of man; (*b*) natural means. The former methods are responsible for far the largest part of modern plant migration. They include (1) dispersal of roots and seeds by farm machinery; (2) conveyance of seeds and bulbs in the earth around the roots of nursery stock; (3) conveyance of seeds in the packing material of warehouse and shop goods; (4) conveyance in hay and other forage; (5) conveyance in impure samples of farm and garden seeds; (6) intentional introduction as useful or ornamental plants, subsequently escaping the garden or farm and becoming naturalised; (7) conveyance from port to port in the ballast of sailing vessels; (8) conveyance in railway trucks, which drop seeds at stations along the road; (9) conveyance by trek oxen and waggons, which drop them along the roadside; (10) conveyance along the tow-path; (11) conveyance by irrigation water.

The natural means are as follow:—(12) spreading by runners as in the tweekgranesk; (13) spreading by underground rhejoines, as in Johnson grass or evergreen millet; (14) spreading by running roots, as in the Canada thistle; (15) special structures of the cupule, enabling it to throw seeds for long distances; (16) the provision of flying apparatus attached to seeds, so that they are carried by the wind—one of the most common methods; (17) drifting by the wind over snow or frozen ground; (18) tumbleweeds; (19) conveyance by floods and streams; (20) burr-weeds, &c., carried in the hair and wool of animals, one of the most common contrivances for distribution; (21) seeds and pieces of plants carried on the feet of water-birds and aquatic reptiles; (22) kraal weeds, the seeds of which pass through animals undigested; (23) spiny fruits and branches carried by animals.

Trout acclimatisation in South Africa, by Mr. B. Bennion. Trout acclimatisation was dealt with generally, and the history of trout acclimatisation in South Africa—in Natal, Cape Colony, and the Transvaal—was given very fully.

The science of bacteriology and its commercial aspects, by Mr. W. H. Jollyman. The object of this paper is largely to answer the question, What practical results accrue from the study of the science of bacteriology? The reply is divided into four sections, showing (1) the assistance the science renders to medicine in the matter of diagnosis of disease; (2) the improved treatment, and consequent lessened mortality resulting from a knowledge of the causal agents; (3) the public health and sanitary science aspects of the study; (4) the work bacteria do in other than medical fields. Towards the end of the paper Mr. Jollyman said, the recent plague epidemic is testimony to the value of bacteriological work; what might have happened had not the early cases been examined bacteriologically one cannot tell, but it is quite certain that the value of an early diagnosis has been incalculable. With regard to the non-pathological side of the question, the remarks made about brewing, butter-making, sewage disposal, soil fertility, &c., will suffice to indicate the commercial value of scientific investigation into these branches. What is going to happen in the future as the result of the study of bacteriology it is impossible to foretell. On the medical side, men are endeavouring to find out more about the causes of human diseases, and to follow up these discoveries by the introduction of specific cures. Veterinary bacteriologists are doing the same work for animals.

In what may be called the bacteriology of the trades, there is no question that there is a great deal to be done; brewing, tobacco-curing, manufacture of organic chemicals—possibly glycerin—and soap manufacture may before long become bacterial work, and so on. In fact, the study of these, the smallest living things known, leads to results of the greatest commercial value.

The bacteriological and other aspects of miners' phthisis, by Dr. L. G. Irvine. The author mentioned the urgent matter of prevention of this disease, and, putting the question as to why the disease should be more prevalent on the Rand than in most other mining centres, he stated that this was due to three reasons. First, the rock was hard and the mines were dry; second, the number of rock-drills used was proportionately great; and third, the quantity of explosives used was also proportionately large.

Notes on some pathogenic bacteria as found in the Transvaal, and their variations from their European prototypes, by Mr. F. H. Joseph.

Papers read before Section C.

Survey practice in the Transvaal, by Mr. P. B. Osborn. The author traced the development of survey practice in the Transvaal from the time of the first crude subdivision of land by the Voortrekkers to the present systematised scientific methods.

Geodetic surveying, by Mr. W. H. Greathead. The author first defined geodetic surveying as the art of surveying extended to large tracts of the earth's surface, in which account must be taken of the curvature of the earth, and proceeded to describe the delicate apparatus and methods used in measuring base lines for the Natal and Cape Colony survey; also the apparatus for the Rhodesian survey.

The mine surveyor and his work on the Witwatersrand, by Mr. A. E. Payne. The present Government is preparing, said the author, to establish the mine surveyor as a professional man. The detailed knowledge of the great variety of subjects coming within the scope of his work is worthy of consideration. He should become the technical adviser of the mine and be encouraged to develop his work from the professional point of view of a mine surveyor.

Fire protection in the mines, by Mr. G. H. Thurston. The Rhodesian tick fever, by Dr. Theiler. Having first pointed out the necessity for preventing the disease by wide publication of the methods to be adopted and by legislation, the author proceeded to discuss the geographical distribution and history of the malady.

The bacterial purification of sewage, by Mr. F. S. Prentice. Some conditions respecting irrigation in the new colonies, by Mr. W. Reid Bell. The blizzard of June 9–12, 1902, by Mr. C. M. Stewart, secretary, Meteorological Committee of Cape Colony. Seldom has South Africa been visited by a snowstorm of such severity, duration, and so extensive as that which started approximately at 6 p.m. on the evening of June 9, 1902, and continued practically without intermission at many places until the morning of June 12. Judging from the barometric readings, this storm seems to have originated in an area of low pressure in the centre of the colony, while the pressure in the west and south was increasing rapidly.

Papers read before Section D.

The handling of young children, by Mr. P. A. Barnett. The author pointed out that by people who recognised no scientific basis for education there is a good deal of random criticism of the efforts made to use systematically the data provided by other sciences. We want more system—not less; though the science of education remains yet to be formulated.

A paper on special assessment was read by Mr. Stephen Court.

Drawing for young children, by Mr. E. B. Sargant. The author said it was well recognised at the present day that the old plan of beginning to teach drawing by making the children produce a series of straight lines tended to disgust young children with the subject for their whole school life. It was much easier to draw circles than straight lines, as appeared natural if the mechanism of the arm was considered. It was also better to begin with drawing rather than with writing, and to practise from the shoulder at first, then from the elbow, and finally from the wrist and fingers. This plan prevented the straining of the eyes at a time when short sight was likely to be produced very early. There was also a great deal to be said for beginning with the brush and colour rather than with the pencil or chalk. Mr. Sargant then proceeded to consider in detail the code of the Orange River Colony, which gave effect in drawing to these principles.

General Business.

At a council meeting of the association on April 4, Sir Charles Metcalfe, the president, alluded to the visit of the British Association to Johannesburg next year, and said he had been in frequent correspondence with members of the committee which had been appointed in England, including Sir Norman Lockyer and Prof. Dewar. Everything is now settled except the route, the fixing of which it has been considered better to postpone until nearer the date. There is also the question as to who should be president for the year, and though this has not been decided yet, there was no doubt there would be a very good president coming out for the meetings. The greatest man of science of the day, Lord Kelvin, who would be eighty-one years of age next year, was resolved to come. With regard to the status of members of the South African Association, they would naturally be entitled to attend all the meetings of the British Association. The proposal was that there should be three days' meetings at Cape Town and three days' meetings at Johannesburg, with shorter sessions at Durban, Kimberley, Bulawayo, and other places visited.

Sir Charles Metcalfe also referred to the arrangements to be made in connection with the visit of the British Association at the annual business meeting of the South African Association. Certain local papers will be read, and these will be chosen by the local committees of the places where meetings are held, so that those who come from distances may have the opportunity of hearing a good paper dealing with the chief object of interest in that particular centre.

THE NEW ZEALAND VEGETABLE CATERPILLAR.

FEW among the smaller natural productions of New Zealand have attracted more attention than the so-called vegetable caterpillar of New Zealand, of which we have just received a very fine specimen from Messrs. Armbrecht, Nelson and Co., of Duke Street, Grosvenor Square, W. Fungoid parasites are sufficiently common in all parts of the world, but are not generally conspicuous enough to be much noticed by any persons but naturalists. Many of the largest and most remarkable moths of the Australian region belong to the families Cossidæ and Hepialidæ, represented in Europe by our goat moth and swifts, and the caterpillars of several species of these are known to be infested by various parasitic fungi belonging to the genus Cordyceps, Fries, which convert the whole substance of the caterpillar into a woody substance, and then sprout from it to a length of several inches.

As in the case of larvæ attacked by insect parasites, these (which are usually about four inches long when full grown) live until they are ready to assume the pupa state, when they bury themselves in the ground, die, and the fungus sprouts upwards, generally from the neck of the caterpillar, sometimes acquiring the length of nearly a foot, and sprouting up from the ground above the caterpillar. Very rarely two, or even three, of these filaments may sprout from a single caterpillar. The best known species is *Cordyceps Hugelii*, Corda (*Sphaeria Robertsii*, Hooker), which is extremely abundant in New Zealand.

"The New Zealander's name for this plant-caterpillar is Hotete, Aweto, Weri, and Anuhe. The natives eat the plants, which when fresh have the flavour of a nut, and also use them, when burnt, as colouring matter for their tattooing, rubbing the powder into the wounds, in which state it has a strong animal smell" (Gray, "Notices of Insects that are Known to Form the Bases of Fungoid Parasites" (1858), p. 6, note quoting from Taylor). Almost every writer in New Zealand has discussed the vegetable caterpillar in more or less detail, notably Taylor and Hochstetter, in addition to Gray's important paper quoted above. Mr. G. Massee's "Revision of the Genus Cordyceps" (*Annals of Botany*, vol. ix. pp. 1–44, pls. i. and ii., March, 1895) may also be consulted.

It is probable that more than one species of New Zealand caterpillar is infested by, perhaps, more than one species of Cordyceps. *C. Hugelii* (*Robertsii*) is usually said to be parasitic on the larva of the large green moth *Hepialus* (*Œnetus*) *virescens*, Doubleday, but Mr. G. V. Hudson points out in his "New Zealand Moths and Butterflies" (p. 132) that this cannot be the case, because the larva of that insect burrows in the wood of trees, and forms its pupa in the galleries, and not in the ground. He suggests that it may infest the larva of *Porina Mairi*, Buller, a brown moth with black and white spots and markings; but this seems equally improbable, for this is a very rare moth, of which very little seems to be known. More information on these curious parasites and their hosts is very desirable.

W. F. KIRBY.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—A meeting of the University Junior Scientific Club was held on May 4. Mr. H. B. Hartley exhibited an unpublished portrait of Sir Richard Owen. Mr. A. S. MacNalty read a paper on William Harvey.

The eleventh Robert Boyle lecture will be delivered on June 3 in Balliol College Hall by Prof. J. J. Thomson, F.R.S. His subject will be "The Structure of the Atom."

The Romanes lecture will be delivered by Sir Courtenay Peregrine Ilbert, K.C.S.I., Balliol College, on Saturday, June 4, at 3 p.m., in the Sheldonian Theatre. The subject of his discourse will be "Montesquieu."

A meeting was held in the schools on Friday, May 6, to discuss the question of the organisation of post-graduate study. The president of Trinity was in the chair. The meeting was largely attended by those who are interested in the encouragement of research. Prof. Poulton moved a resolution advocating the expediency of "the further utilisation of fellowships for the purposes of research." This was seconded by Profs. Ellis and Gardner, and carried unanimously. Dr. Farnell moved a resolution favouring "the better organisation of the teaching resources of Oxford." He wished to see the boards of faculty take a more active part in organising the teaching resources, which now suffer from considerable dislocation. The boards ought to be able to give the status of professor to a college tutor, and assign him an income from university funds. The general principle of Dr. Farnell's resolution was carried.

CAMBRIDGE.—Sir Michael Foster has been re-appointed a manager of the Balfour (Animal Morphology) Fund.

Applications for leave to occupy the university tables at the Naples and Plymouth Zoological Stations are to be sent to Dr. Harmer, King's College, by May 26.

Mr. Frank G. Smart, M.B., has generously endowed a university studentship for research in botany of the value of 100*l*. a year for two years. The first election will be made in July.

The Board of Agricultural Studies reports the continued progress of the department, which last term had forty students. A number of field experiments have been instituted, and are in progress on the university farm and in the adjoining counties, under the supervision of Prof. Middleton and his staff.

THE Drapers' Company has decided to grant 15,500*l*. to the University College of South Wales for the purpose of erecting the structure of the proposed new library, in lieu of 10,000*l*. conditionally granted in 1895.

IT is announced in *Science* that at the recent Convocation of the University of Chicago, President Harper acknowledged a gift of 1000*l.* for special investigation in the department of physics, by the president of the board of trustees, Mr. Martin A. Ryerson, and a gift of 2000*l.* by Miss Helen Snow as a memorial to George W. Snow, her father, to rebuild the horizontal telescope at Yerkes Observatory, which was injured by fire.

AMONG the many educational enterprises of the Lancashire County Council, the system of technical instruction for fishermen, which is being much appreciated by the fishermen along the Lancashire coast, deserves special comment. The county council has arranged for batches of fifteen fishermen at a time to attend at the Piel (Barrow) Hatchery and Marine Laboratory to be instructed in the habits and conditions of breeding of various kinds of fish. The course lasts a fortnight, during which time the fishermen reside at Piel. The county council allows each man 5*l.* towards his expenses. We have received from Prof. W. A. Herdman, F.R.S., a copy of the syllabus of the lessons in marine biology given in these practical classes, and it shows that in addition to an introductory course, time is found for the fishermen to dissect and study the mussel, shrimp, crab, cockle, oyster, and fish parasites, and also to become acquainted with the leading facts about the breeding of these and other forms of life. Such courses of work as these must be of great value to fishermen.

IN his presidential address to the British Association last year, Sir Norman Lockyer used the two-power principle by which our naval expenditure is determined to illustrate and emphasise his appeal for State aid for universities equivalent to any two nations commercially competing with us. Recognising that universities are the chief producers of brain-power, and therefore the equivalents of battleships in relation to sea-power, examination was made of the provision for university education in Germany and the United States and that existing in this country. The result showed clearly that "instead of having universities equalling in number those of two of our chief competitors together, they are by no means equal to those of either of them singly." In connection with this comparison, it is of interest to notice that in answer to a question asked in the House of Commons last week, the average annual cost of maintaining in commission a first-class battleship of about 13,000 tons was stated to be, in round numbers, 94,000*l.* The State contribution to the whole of our universities and colleges amounts to about 156,000*l.* a year, that is, less than the sum required to keep two battleships in commission.

IN a dedication address at the opening of Palmer Hall, Colorado, Prof. S. Lawrence Bigelow dealt with the growth and function of the modern laboratory. The address is printed in *Science* of April 22. Eighty years ago, said Prof. Bigelow, there was not, in any country, a single laboratory for the purpose of teaching chemistry, though, of course, the subject had been taught for many years by means of lectures forming a recognised part of a medical course. To Liebig, at Giessen, belongs the credit of establishing the first chemical laboratory ever opened to students in a university. This was soon after 1824, the year in which he began his work at Giessen. So far as the foundation of laboratories in America is concerned, the address states that chemistry was taught in the laboratory in the medical department of Harvard University at an early date, and in 1846 a new medical school was built, the basement of which was devoted to a chemical laboratory capable of accommodating 138 students. At Yale Prof. B. Silliman and his son established a laboratory of analytical chemistry, and it became of sufficient importance to be incorporated as part of the university in 1847. The University of Michigan is generally recognised as being the first to introduce the laboratory method in teaching. A building exclusively for the teaching of chemistry was finished in this university at a cost of 1200*l.*, including the equipment, and was in use in 1856. But, as Prof. Bigelow remarked, it would be harder to find a university without moderately good laboratories to-day than it was to find one with them in 1850. The concluding sentences of the address will appeal to all men of science:—"Our laboratories have overwhelmingly justified their cost by their past history, and are justified in making greater demands than ever, by the importance of the functions which they fulfil. It is to be hoped that philanthropists will be still more liberal than they have been, and that the people will tax themselves more than they ever have, through their legislatures, to give to all schools, colleges and universities. Such money is the fire insurance and the life insurance of society as a whole, guaranteeing the maintenance of law and order, and the ability of the next generation to support the burden of advancing civilisation, when its turn comes."

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, February 25.—"On the Compressibility of Solids." By J. Y. **Buchanan**, F.R.S.

The solids dealt with in this research are the metals platinum, gold, copper, aluminium, and magnesium. Their absolute linear compressibilities were directly determined at pressures of from 200–300 atmospheres at temperatures between 7° and 11° C. The determinations were made by the same method, and with the same instrument which the author used for the determination of the compressibility of glass in 1880 (Roy. Soc. Edin. *Trans.*, vol. xxxix. p. 589).

The instrument consists essentially of a powerful force pump and a tubular receiver to take the samples of metals to be experimented on. These must have the form of rod or wire. The steel tube which forms the receiver has a length of 75 inches and an internal diameter of 5/16 inch. It is closed at each end by thick glass tubes having a bore of between one and two millimetres. In the present investigation the metals were all used in the form of wire (No. 22 S.W.G.). Inside the steel tube they are supported in an axial position by an internal concentric tube, and their ends project into, and are visible through, the glass terminals. Each glass terminal is commanded by a microscope with micrometer eye-piece and standing on a substantial platform, altogether independent of the rest of the apparatus. When the wire is properly placed in the receiver and the microscopes are in position, the pressure is raised to the desired height, as indicated by the manometer, and the ends of the wire are observed and their positions with reference to the micrometers noted. The pressure is then carefully relieved, and a displacement of both ends is seen to take place and its amplitude is measured. The sum of the displacements of the ends, regard being had to their signs, gives the absolute expansion of the wire in the direction of its length, when the pressure on its surface is reduced by the observed amount, and consequently also the compression when the process is reversed. From this the linear compressibility is at once obtained. If the mass of the wire be isotropic, then its cubic compressibility is obtained by multiplying the linear compressibility by three. The wires used were all well annealed before the experiment, with the exception of the magnesium.

In order to bring the ends into a suitable position for observation with the microscopes, the length of the wire had to be between 75 and 75·5 inches. The actual length was measured exactly in each case, and it averaged 75·32 inches (1·913 metres).

The manometer which indicates the pressure in the instrument is simply a mercurial thermometer with a very thick bulb. The scale on it is an arbitrary one, and its value as a measure of pressure is fixed by observing its reading in comparison with the principal piezometer which was used by the author during the voyage of the *Challenger*. The standard of pressure is therefore an open-air column of sea-water of known properties. The micrometers in the eye-pieces of the microscopes were standardised by reference to a stage micrometer which was verified at the National Physical Laboratory. Their values were very nearly equal, with the powers used. One division in the eye-piece corresponded to 0·000422 and 0·000417 inch respectively on the stage, or to about 1/180000 of the length of the wire.

In the paper the results for each metal are given in a separate table. It will be sufficient to reproduce the summary, Table I. In it the compressibilities of English

flint glass and of the glass of which ordinary German tubing is made, as well as that of mercury, have been included for purposes of comparison. The compressibility of mercury rests upon a large number of observations made in the *Challenger* (Chem. Soc. *Journ.*, 1878, vol. xxxiii. p. 453).

Table I.—Summary.

Substance	Year	Atomic Weight	Density	Compressibility	
				Linear	Cubic
Platinum... ...	1904	194	21·5	0·1835	0·5505
Gold	,,	197	19·3	0·260	0·780
Copper	,,	63	8·9	0·288	0·864
Aluminium ...	,,	27	2·6	0·558	1·674
Magnesium ...	,,	24	1·75	1·054	3·162
Mercury	1875	200	13·6	1·33	3·99
Glass, flint ...	1880	—	—	0·973	2·92
,, ,, ...	1904	—	2·968	1·02	3·06
,, German	,,	—	2·494	0·846	2·54

It is pointed out that the number of metals experimented on is too small to permit any confident generalisation.

It will, however, be observed that in the case of the five metals used as wire, their compressibility increases as their density and atomic weight diminish, yet there is no reason to suppose that the compressibility is a continuous function of the atomic weight, like the specific heat. Mercury, although in the fused state, shows this clearly. But besides this, it happens that two pairs out of the five metals, namely, platinum-gold and aluminium-magnesium, are contiguous in the atomic weight series, yet the compressibility of magnesium is, roughly, double that of aluminium, and the compressibility of gold is half as much again as that of platinum. If, however, we compare gold and copper, which occupy parallel positions in Mendeléeff's scheme, we see that they are very much alike, and the same holds with regard to magnesium and mercury, which occupy a homologous position. If these facts indicate anything more general, we should expect the metals of the palladium and iron group to have a low compressibility like platinum, zinc and cadmium to have a very high compressibility like magnesium, and thallium an intermediate but still considerable compressibility like aluminium.

It will be observed that the two kinds of glass mentioned in Table I. are more compressible the greater their density. This may, however, be due to a specific feature of the oxide of lead which enters largely into the composition of the flint glass.

Referring to the use of glass exposed to high internal pressure, the author says:—In the work connected with this paper, which extended over the greater part of four weeks, fifteen glass terminals gave way, and oddly enough, the failures were as nearly as possible equally distributed between the two ends; eight of them fell to the left arm and seven of them to the right arm. The bursting of a terminal causes no inconvenience beyond the trouble of replacing it, because the construction of the instrument enables air to be completely excluded from it, and the quantity of water in it to be kept within such limits that its resilience is of no account. When a tube bursts it usually splits longitudinally up the middle into two slabs. One of these almost always remains entire; the other is sometimes broken into fragments, but there is never any projection of material unless the instrument has been carelessly put together and air admitted. The paper concludes with an account and an illustration of some curious *microseismic effects* produced on the wires by the explosion of the glass terminals.

Geological Society, April 13.—Dr. J. E. Marr, F.R.S., president, in the chair.—The discovery of human remains under the stalagmite-floor of Gough's Cavern, near Cheddar: H. N. **Davies**. Gough's Cavern opens at the base of the cliffs on the south of Cheddar Gorge. Human and animal remains have been discovered at different times. The principal deposits are a stalagmite-like travertine overlying cave-earth. When excavating part of a fissure running northward a human skeleton was discovered, associated with flakes, scrapers, and borers of flint, embedded in cave-earth. The remains of the skeleton excavated comprise the skull, the bones of an arm, a leg, and part of the pelvic girdle. The other bones were allowed to remain *in situ*, and may now be seen. The position of the skeleton was that which would have been assumed by a drowned man. Interment is unlikely, because of the shape of the fissure, which was choked up with débris and calcareous deposits. The stature of the man was 5 feet 5 inches; he was of muscular build, with prognathous jaws, a straight thigh, a platycnemic tibia, and a thick dolichocephalic skull. The animal remains found in the cave-earth of other parts of the cavern are those of mid- and late Pleistocene age, and this evidence, together with that derived from the position and character of the skeleton, and the workmanship of the flakes, points to a period towards the close of the Palæolithic or the opening of the Neolithic age.—History of volcanic action in the Phlegræan Fields: Prof. Giuseppe **De Lorenzo.** The author recognises three chief periods in the volcanic history of the district:—(1) The eruptions which took place under the sea during the Pleistocene period. Their surviving products can be grouped in two divisions. The older of these (*a*) is represented by the piperno and grey pipernoid tuffs of the Campania. These deposits consist of grey trachytic tuff, with scattered black scoriæ, and with a varying proportion of non-volcanic sediment. The vents whence they were ejected are now no longer to be traced. The author is disposed to regard the piperno as a trachytic lava with schlieren, the dark lenticles being made up of such minerals as augite, ægirine, and magnetite, while the lighter matrix is felspathic (anorthose) with a spherulitic structure and microliths of ægirine and augite. The second phase (*b*) of the first eruptive period is represented by ashes, lapilli, pumice, and sands, intercalated with marine shell-bearing clays and marls, and also with conglomerates and breccias. (2) Above the records of the first volcanic period lie those of the second—the yellow tuff, which forms the most characteristic of the volcanic formations of the Phlegræan Fields. It is a yellow, compact, well stratified aggregate of trachytic detritus, through which are scattered fragments of tuff and lava. Its average thickness exceeds 300 feet. It was a submarine accumulation. Owing to the uniformity of its lithological characters, this tuff has not furnished evidence of a definite order of succession in the eruptions to which it was due. It is possible to recognise vents from which the tuff was discharged. (3) After the discharge of the yellow tuff the volcanic tract appears to have been upraised into land, and to have been exposed to a period of subaërial denudation. Vents made their appearance and discharged fragmental materials, differing from the tuff in showing a greater variety of composition, and in the proofs which they furnish of a succession of eruptions, and a gradual southward shifting and diminution of the eruptive energy. The largest and most ancient of the volcanoes of this latest period is that of Agnano. Not improbably it was from this eruptive centre that the trachy-andesitic lava of Caprara issued. The crater-lake of Avernus belongs to the latest group, and perhaps it was the water percolating from this basin to the thermal springs of Tripergole which, in September, 1538, gave rise to the explosion that built up Monte Nuovo—the youngest of the cones of the Phlegræan Fields.

Entomological Society, April 20.—Dr. F. A. Dixey, vice-president, in the chair.—Mr. M. **Jacoby** exhibited a ♂ specimen of the beetle *Sagra senegalensis* with ♀ characters, received from Mr. Barker in Natal.—Dr. Norman **Joy** exhibited *Orochares angustata*, Ev., taken at Bradfield, Berks., in December, 1903—the second recorded British specimen; a species of Tychius, which he said might be a variety of *Tychius polylineatus*, Germ. (not now included in the British list), or, more probably, a new species closely allied to it, taken near Streatley, Berks., last year; and two specimens of *Pselaphus dresdensis*, Herbst., taken near Newbury this year.—Mr. C. O. **Waterhouse** exhibited an unnamed species of Nemoptera from Asia Minor, resembling *Nemoptera huttii* from Australia.—Mr. F. **Enock**

read a paper on nature's protection of insect life, illustrated by colour photography, and exhibited a number of lantern slides.—Mr. P. I. **Lathy** communicated a paper on new species of South American Erycinidæ.—Major Neville **Manders,** R.A.M.C., communicated some breeding experiments on *Catopsilia pyranthi,* and notes on the migration of butterflies in Ceylon.—A discussion followed on specimens of the dipterous families Stratiomyidæ to Crytidæ, opened by Mr. G. H. **Verrall,** who said the object of the discussion was to determine the number and distribution of the British species comprised in these families. Colonel J. W. Yerbury said that on behalf of Prof. Poulton he had been asked to exhibit some specimens the interest of which mainly lay in the specific names used, which names were useful as showing the nomenclature employed by a past school of dipterologists, and might give a clue to the manner in which some reputed species have found their way into the British list. He directed special attention to *Ephippiomyia ephippium,* an insect reputed to have been taken at Combe and Darenth Woods, but which was without doubt of German origin; *Isopogon brevirostris,* probably the identical specimen referred to in Curtis's "British Entomology" as having been taken on The Devil's Ditch, Newmarket; and *Laphria marginata,* stated to have been bred from a hornet's nest. Mr. Colbran J. Wainwright, exhibiting two specimens of Anthrax, said that hitherto Mr. Verrall had believed that we had lost two certain species of Anthrax in this country, *A. fenestratus* and *A. paniscus.* His two specimens, though allied to *A. paniscus,* were abundantly distinct. One had been taken by Mr. R. C. Bradley at Bournemouth, the other by Mr. W. G. Blatch at Poole, but at present no name could be given to the species.

Chemical Society, April 20.—Prof. W. A. Tilden, F.R.S., president, in the chair.—The following papers were read:—The vapour density of hydrazine hydrate: A. **Scott.** The author finds that at 98°·8 the vapour density is 15·8 instead of 25 as required by N_2H_6O; at 138° the dissociation into $N_2H_4+H_2O$ is complete, and at higher temperatures a certain amount of decomposition into nitrogen, ammonia and water occurs.—The combining volumes of carbon monoxide and oxygen: A. **Scott.** The results of the author's experiments indicate that the molecular concentration of carbon monoxide is slightly greater than that of oxygen, the combining volumes being CO : O : : 1·9985 : 1 with carbon monoxide from calcium oxalate, and 1·9994 : 1 with that from formic acid.—A revision of the atomic weight of rubidium: E. H. **Archibald.** The mean values of the atomic weight of rubidium obtained from fourteen analyses were 85·490 and 85·484 from the ratios AgCl : RbCl and Ag : RbCl respectively. Analyses of rubidium bromide led to the value 85·483, obtained from either of the ratios AgBr : RbBr or Ag : RbBr.—Experiments on the synthesis of the terpenes, part i., synthesis of inactive terpineol, dipentene and terpin hydrate: W. H. **Perkin,** jun. Pentane-$\alpha\gamma\epsilon$-tricarboxylic acid, when digested with acetic anhydride and subsequently distilled, is converted into δ-ketohexahydrobenzoic acid. The ester of this acid reacts readily with magnesium methyl iodide, yielding *cis*-δ-hydroxyhexahydro-*p*-toluic acid, which with fuming aqueous hydrobromic acid is converted into δ-bromohexahydro-*p*-toluic acid, which in turn yields Δ^3-tetrahydro-*p*-toluic acid when heated with pyridine and sodium carbonate. The ester of the latter with an excess of magnesium methyl iodide yields terpineol. From the synthetic terpineol so obtained dipentene and terpin hydrate were readily prepared in the normal manner.—A lævorotatory modification of quercitol: F. B. **Power** and F. **Tutin.** The lævorotatory modification described by the authors was obtained from the leaves of *Gymnema sylvestre,* a plant belonging to the family Asclepiadaceæ, and indigenous to Banda and the Deccan Peninsula.—The constituents of the essential oil of Californian laurel: F. B. **Power** and F. H. **Lees.** The Californian laurel, *Umbellularia californica,* yields an essential oil with a pale yellow colour and an odour at once aromatic and irritant. It was found to contain eugenol, *l*-pinene, cineol, safrole, eugenol methyl ether, veratric acid, and a new, unsaturated, cyclic ketone, *umbellulone,* $C_{10}H_{14}O$. To the last of these the peculiar pungency of the oil is due.—Some derivatives of umbellulone: F. H. **Lees.** A description of derivatives of umbellulone.—Ammoniacal double chromates and molybdates: S. H. C. **Briggs.** The compounds

$$CuCrO_4,3\tfrac{1}{2}NH_3,\tfrac{1}{2}H_2O;\ CuMoO_4,2NH_3,H_2O;\ CuWO_4,4NH_3\ \text{and}\ ZnWO_4,4NH_3,3H_2O$$

have been prepared and are described in the paper.—The hexahydrated double chromates. Magnesium and nickel compounds: S. H. C. **Briggs.**—Bornylcarbimide: M. O. **Forster** and H. M. **Attwell.** A description of this and related substances.—Reduced silicates: C. **Simmonds.** The substance left when lead silicates are reduced by heating in hydrogen is shown to be a compound which can be regarded as a combination of the metal and silica, in the same sense as the original silicate is a combination of the metallic oxide and silica. Similar results were obtained with the silicates of copper, iron, nickel and cobalt.—Picryl derivatives of urethane and thiourethane: J. C. **Crocker** and F. H. **Lowe.** The authors show that the reaction between picryl chloride, thiocyanates and alcohols is due to the formation of the ψ-thiourethanes of the type PiN : C(SH).OX as intermediate products, which subsequently react with picryl chloride and pass into the picriminothiocarbonates PiN : C(SPi).OX.—The oxime of mesoxamide and some allied compounds, part iii., tetrasubstituted derivatives: M. A. **Whiteley.** A description of a number of these compounds is given.

Royal Microscopical Society, April 20.—Dr. Hy Woodward, F.R.S., vice-president, in the chair.—A large tank microscope, made by Thomas Ross, presented to the society by the committee of the Quekett Microscopical Club, was exhibited. It was made not later than the year 1870, and was designed for the purpose of examining objects contained in aquaria.—The annual exhibition of pond life was given this evening by fellows of the society, assisted by members of the Quekett Microscopical Club.

Paris.

Academy of Sciences, May 2.—M. Mascart in the chair.—The action of terrestrial magnetism upon a tube of nickel steel (invar) intended for use as a geodesic pendulum: G. **Lippman.** The alloy of nickel and iron known as *invar,* which possesses a coefficient of expansion only one-twentieth that of brass, has obvious advantages for pendulum observations. This steel, however, is magnetic, and it was thought possible that the disturbing influence introduced in this way might be too large to be neglected. The magnetic moment of a tube of this material was determined, and the possible error on a pendulum observation calculated. It was found to be negligible, and hence invar can be advantageously substituted for brass in the pendulum.—The effect of small oscillations of the external action on systems affected with hysteresis and viscosity: P. **Duhem.**—Geodesic and magnetic work in the neighbourhood of Tananarive: P. **Colin.**—Polyvalent antipoison serums. The measurement of their activity: A. **Calmette.** The antihæmolytic power is a measure of the antitoxic power of a serum, and a method is described by which the former can be determined in glass.—Observations of the Brooks comet (1904 *a*) made with the bent equatorial at the Observatory of Lyons: J. **Guillaume.**—On a new apparatus for measuring the power of motors: Ch. **Renard.** The axle of the motor is connected to a bar carrying two aluminium vanes, the latter being capable of adjustment as regards their distance from the axis. This having been previously calibrated against a dynamometer, the determination of the horse-power of a motor is reduced to the determination of the angular velocity.—The Adolphe bridge at Luxembourg (1899–1903): M. **Séjourné.**—On the comparison of spectro-photometric determinations: P. **Vaillant.**—The sensibility of the azimuth balance: V. **Crémieu.** An extension of the theory of the azimuth balance, a description of which has been given in an earlier paper.—On the *rôle* of the centrifugal force component in the determination of the sense of rotation of cyclones and water vortices: Bernard **Brunhes.**—On the electrolytic solution of platinum. A new method for preparing platinocyanides: André **Brochet** and Joseph **Petit.** When platinum is used as the anode in a solution of potassium cyanide, it remains unattacked. With an alternating current the platinum is readily attacked, a

current density of 20 to 80 amperes per square decimeter dissolving from 0·4 to 0·6 gram per ampere hour. With barium cyanide, barium platinocyanide is formed by the action of the alternating current; the yield of the platinocyanide is good.—The origin of the Blondlot rays given off during chemical reactions: Albert **Colson.** Chemical reactions in which Blondlot rays are given off are always accompanied by physical actions, such as contraction or cooling.—On cacodylic acid and amphoteric bodies: P.-Th. **Muller** and Ed. **Bauer.** Different physicochemical methods all lead to the same conclusion, that cacodylic acid and its sodium salt have the same constitution; it follows that an amphoteric body is not necessarily a pseudo-acid.—The reduction of silica by hydrogen: A. **Dufour.** Silica is reduced at a high temperature by hydrogen, water and hydrogen silicide being formed. The inverse reaction is possible. This reduction explains the phenomenon of devitrification of silica tubes when heated in the blowpipe, and also gives a satisfactory explanation of the experiments of Boussingault and of Schutzenberger on the formation of the silicide of platinum by silica at a distance in a current of hydrogen.—On the zinc aluminium alloys: Hector **Pécheux.** By treating zinc with aluminium in various proportions, nine different well defined alloys have been obtained, the physical and chemical properties of which are described.—The action of diazobenzene chloride upon diphenylamine: Léo **Vignon** and A. **Simonet.** Phenyldiazoamidobenzene is obtained in this reaction.—On allyl and propenyl-alkyl ketones: E. E. **Blaise.**—The application of the Grignard reaction to the halogen esters of tertiary alcohols: L. **Bouveault.** By carefully regulating the temperature the chloride of tertiary butyl alcohol reacts normally with magnesium; the product absorbs carbon dioxide, giving pivalic acid. The reaction with ethyl formate was also studied.—On the symmetrical dichloromethyl ether: Marcel **Descudé.** Trichloride of phosphorus and polyoxymethylene react on heating in the presence of a little zinc chloride, giving a good yield of the above substance.—On a method of isolating cytoplasmic substances: Maurice **Nicloux.**—New researches on aucubine: Em. **Bourquelot** and H. **Hérissey.**—Abnormal hybrids: C. **Viguier.**—On the biology of *Sterigmatocystis versicolor*: Henri **Coupin** and Jean **Friedel.**—A food substance obtained from the pith of the Madagascar palm: R. **Gallerand.** The flour made from this palm is distinguished by its richness in albumenoid matter, of which it contains 10·5 per cent.—On the presence of tin in the department of Lozère: Marcel **Guédras.**—Nervous oscillations studied by means of the *n*-rays emitted by the nerve: Augustin **Charpentier.**—The modifications undergone by the digestive apparatus under the influence of diet: Camille **Spiess.**

DIARY OF SOCIETIES.

THURSDAY, May 12.

Institution of Electrical Engineers, at 8.—If the discussion on Messrs. Merz and McLellan's paper is concluded at the meeting of May 5, Messrs. Parsons, Stoney and Martin's paper on the Steam Turbine as applied to Electrical Engineering will be read and discussed.

Mathematical Society, at 5.30.—Some Mathematical Instruments: C. Cooke (communicated by Major P. A. MacMahon).—On the Evaluation of Certain Definite Integrals by Means of Gamma Functions: A. L. Dixon.—Generalisations of Legendre's Formula

$$KE'-(K-E)K'=\tfrac{1}{2}\pi:$$

A. L. Dixon.—Note on the Integration of Linear Differential Equations: Dr. H. F. Baker.—On Perpetuant Syzygies: A. Young and P. W. Wood.

Society of Arts, at 4.30.—British Grown Tea: A. G. Stanton.

FRIDAY, May 13.

Royal Astronomical Society, at 5.—Milky Way Charts of the Heavens to Argelander's Scale 1°=20mm., with description by H. Dennis Taylor and Alfred Taylor of the Lenses and Mount: J. Franklin-Adams.—Methods of Correcting Moon's Tabular Longitude: P. H. Cowell.—The Definitive Places of the Standard Stars for the Northern Zones of the Astronomische Gesellschaft: A. M. W. Downing.—Note on the Formulæ connecting "Standard Coordinates" with Right Ascension and Declination: F. W. Dyson.—*Probable Paper*.—On the Pivot Errors of the Radcliffe Transit-Circle: A. A. Rambaut.—On the new Greenwich Micrometer for Measurement of Photographs of Eros: Communicated by the Astronomer Royal.—Further Analyses of the Moon's Errors with the Mean Elongation as Argument: P. H. Cowell.

Malacological Society, at 8.—List of Mollusca collected during the Commission of H.M.S. *Waterwitch* in the China Seas, 1900–1903, with Descriptions of New Species: Surgeon K. Hurlstone Jones, R.N., and H. B. Preston.—On a Carboniferous Nautiloid from the Isle of Man: G. C. Crick.—Notes on the Genus Anoma: E. R. Sykes.—New Land Shells from New Zealand: Henry Suter.

MONDAY, May 16.

Sociological Society at 5.—Eugenics; its Definition, Scope and Aims: Francis Galton, F.R.S.

Royal Geographical Society, at 3.—Anniversary Meeting: Address by the President.

TUESDAY, May 17.

Royal Institution, at 5.—Meteorites: L. Fletcher, F.R.S.

Zoological Society, at 8.30.—On some Nudibranchs from East Africa and Zanzibar. Part v.: Sir Charles Eliot.—Description of a new Tree-Frog of the Genus Hyla, from British Guiana, carrying Eggs on the Back: G. A. Boulenger, F.R.S.—Notes upon the Anatomy of certain Boidæ: F. E. Beddard, F.R.S.

Royal Statistical Society, at 5.—Local Expenditure and Local Indebtedness in England and Wales: R. J. Thompson.

Society of Arts, at 8.—Pewter and the Revival of its Use: Lasenby Liberty.

WEDNESDAY, May 18.

Royal Microscopical Society, at 8.—Note on Grayson's Rulings: E. M. Nelson.—Exhibition of Flower Seeds under Microscopes: C. Beck.

Chemical Society, at 5.30.—Action of Nitrosyl Chloride on Pinene: W. A. Tilden.—The Electrolytic Estimation of Minute Quantities of Arsenic: H. J. S. Sand and J. E. Hackford.—The Decomposition of the Alkylureas (a Preliminary Note): C. E. Fawsitt.—The Action of Sodium Methoxide and its Homologues on Benzophenone Chloride and Benzal Chloride. Part ii: J. E. Mackenzie and A. F. Joseph.—The Formation of Periodides in Nitrobenzene Solution, II. Periodides of the Alkali and Alkaline Earth Metals: H. M. Dawson and Miss E. E. Goodson.

THURSDAY, May 19.

Royal Society, at 4.30.—The Bakerian Lecture will be delivered by Prof. E. Rutherford, F.R.S., on the Succession of Changes in Radio-active Bodies.—The following papers will probably be read in title only:—On Saturated Solutions: Earl of Berkeley.—On the Liquefied Hydrides of Phosphorus, Sulphur, and the Halogens, as Conducting Solvents. Part i.: B. D. Steele and D. McIntosh. Part ii.: D. McIntosh and E. H. Archibald.—On the General Theory of Integration: Dr. W. H. Young.

Institution of Mining and Metallurgy, at 8.—Miners' Phthisis—its Causes and Prevention: Dr. J. S. Haldane and R. A. Thomas.

Institution of Electrical Engineers, at 8.—Discussion on Messrs. Parsons, Stoney and Martin's paper, entitled The Steam Turbine as applied to Electrical Engineering.

FRIDAY, May 20.

Royal Institution, at 9.—The Radiation and Emanation from Radium: Prof. E. Rutherford, F.R.S.

CONTENTS.

THURSDAY, MAY 19, 1904.

THE STRUCTURE OF AUSTRIA-HUNGARY.

Bau und Bild Österreichs. By Carl Diener, Rudolf Hoernes, Franz E. Suess, and Victor Uhlig. Pp. xxiv+1110. (Vienna: F. Tempsky; Leipzig: G. Freytag, 1903.) Price 78 kronen, or 65 marks.

THE publication of this elaborate and serious work implies a high regard for scientific education in the countries for which it is immediately intended. It is not a popular correlation of the scenic and geological features of the Austro-Hungarian Empire, such as would appeal to the ordinary traveller; and yet, now that it has appeared, we feel that no one can properly understand the regions dealt with until he has consulted this treatise, and thus brought himself abreast with current views. We recently had occasion to notice (NATURE, vol. lxviii. p. 550) the admirable series of brochures prepared in Vienna for the Geological Congress of 1903. The Bosnian guide then foreshadowed has since appeared, and sums up a surprising amount of recent observations made in the occupied provinces. But these publications do not detract from the value of the great work now before us, which is essentially a book for the library, clear, readable, and stimulating. Its reviews of successive opinions on this or that controverted area are of considerable mental value, and the authors state their own conclusions with a display of argument and reasoning that is rare in works of reference. As in a good deal of Austrian writing, the human man, scaling the hillside, or watching the great rivers swirling through the plains, is apparent through the topographical and geological details; and even the pages on petrography, when thus led up to, have an impression of the open air.

Prof. Eduard Suess contributes an introduction, in which he relates the growth of geological observation in the empire, from the mining operations of the sixteenth century to Partsch and Haidinger in 1850. The Bohemian region is then dealt with by Franz E. Suess in 322 pages, accompanied by landscape-illustrations that convey much of the character of the country. We thus see the white quarry on the Schlossberg of Brüx, the pastures of Eisenstein under the forest-rim, and one of the great black open workings of the brown-coal area in the north. The author shows well how the Bohemian region spreads beyond political Bohemia, and that, while watersheds divide nations, the boundaries of hill and plain define geological areas. If we reach Eisenstein, for example, we must go forward and make the plunge through the Bavarian forest to the Danube; on the other hand, the easy undulating country beyond Habern leads us inevitably to inquire into the structure of Moravia. While the great Bohemian "horst" is part of a range that arose during the movements of Middle Carboniferous times, its fundamental rocks are largely pre-Cambrian. The central granites have penetrated these gneisses and phyllites at a period which may be later (p. 56) than the Ordovician, and have profoundly modified and intermingled with the gneisses. The schists, on the other hand, possibly through their having been nearer the surface at the time of the intrusion, show a fairly sharp line of contact. Similar phyllites appear in Moravia in the cores of gneissic anticlinals, reversing the usual relations of such masses. Unless thrust-planes can be called in, it is clear that this region offers much room for speculation. Dr. F. E. Suess (p. 76) urges that considerable movements took place in Moravia before the great bow of old rocks, stretching from the Sudetic to central France, was folded and upheaved in the Carboniferous period. This is rendered likely by the antiquity of the rocks themselves, and is supported by the occurrence (p. 114) of pebbles of the early gneisses and amphibolites in pre-Cambrian conglomerates near Příbram.

The famous question of Barrande's "colonies" is dealt with historically and succinctly (p. 141). Among other interesting details, we can only refer to the evidence for the existence of central European deserts in Permian times; to the almost complete absence of marine Mesozoic deposits from Bohemia until the entry of the amazingly world-wide Cenomanian sea (p. 166); and to the comparatively recent origin of some of the ore-deposits in the Erzgebirge (p. 243). An excellent coloured map concludes this section.

Dr. C. Diener then enters on his difficult task of describing the Eastern Alps and the Dinaric Karst. He traces the central zone from the Swiss border, until it breaks off against the incurving areas of subsidence on the fringe of the Pannonian plain. The gneissic axis of northern Styria alone survives, and connects the Alps below Vienna with the Karpathians. While the author's debt to Prof. E. Suess is manifest and acknowledged, he feels bound to join those critics who regard the Alps as resulting from lateral thrusts in two opposite directions, instead of from a one-sided action (pp. 637 and 641). He is unable to recognise, either from the lie of the folds or from the curve of the whole chain, the outer from the inner side of a mountain system. The Dinaric folds thus present their concave side to the Servian mass against which they have been pressed, while the area of subsidence occupied by the Adriatic lies on the concave side of the Alps and on the convex side of the Dinaric system. Very many geologists will agree with Dr. Diener when he says of the southern Alps,

> "Hebung, nicht Senkung, ist also hier der Effekt der Zusammenfaltung gewesen. Eine wirkliche Senkung hat nur bei dem jüngeren Einbruch des Adrialandes stattgefunden" (p. 638).

The remarkably late origin of the Adriatic subsidence is emphasised on pp. 607 and 629, the alluvial sands of southern Istria being probably involved, and the movements being certainly post-Pliocene. The Alps, on the other hand, are regarded as having remained stationary at this epoch, in opposition to the views of Dr. Heim.

The island-like masses of folded rocks that rise, as a welcome feature, above the lower Sava plain are once more regarded as the partially buried spurs of the eastern Alps (p. 566), and not as portions of an older system. Dr. Diener finds himself also opposed to the torsional views of Mrs. Ogilvie-Gordon in re-

gard to the huge blocks of dolomite in Tyrol (p. 548), and believes that these weighty masses have sunk down amid the yielding tuffs and sediments deposited upon their flanks. The reef problem is dealt with cautiously (p. 541, &c.), and the term "reef" is used, following Prof. Suess, as the equivalent of "massive unstratified limestones and dolomites," rising amid strikingly contrasted sediments. It is unfortunate that the latest evidence brought forward by Mrs. Ogilvie-Gordon as to the age of the igneous intrusions round Predazzo was published too recently to receive adequate notice in this volume, though her arguments and those of Rothpletz are briefly mentioned.

For those who desire a general history of the Alps, adorned with modern references, we may commend the whole seventh "Abschnitt" (pp. 589–610) as a clear and even spirited summary. The discussion of mountain-structure that follows shows the independence and vitality of the school which Suess has founded in Vienna, a school of progressive inquiry unhampered by dogmas, active in unearthing problems, but willing to wait for explanations.

Dr. V. Uhlig is given 260 pages for the exposition of the Karpathian lands, and occupies them with admirable clearness. Like his predecessor, he balances arguments, and states his own conclusions with the modesty of a true explorer. This is particularly noticeable (p. 904, &c.) in his account of the origin of the central *massif* of the Karpathians, which he regards as pushed up by pressure from all sides into and partly through its former Mesozoic covering. One-sided tangential movement will not, in his opinion, in any way satisfy the facts observed (p. 910).

The illustrations and sections accompanying Dr. Uhlig's descriptions are more than usually attractive. We see patches of Eocene conglomerate resting on the central granite of the Tatra, and crystalline schists, on the other hand, thrust up over Neocomian limestone at Bárat Lehota, and sending off dyke-like tongues into the cracks opened in the latter. The fascinating question of the "Klippenzone," referred to by us in a previous review, receives full treatment. The beautiful landscape on p. 771 recalls many of the deep wooded valleys, among sheer limestone cones, which intersect the frontier lands of Arva. The tempting theory that the "Klippen" float as detached fault-blocks amid the softer Flysch deposits is set aside (pp. 791–4), in face of the banks of Upper Cretaceous conglomerate worn from them, and found so repeatedly against their flanks. Examples of these occur from the west end of the chain down to Transylvania (p. 809).

The great Flysch or Karpathian Sandstone series has yielded foraminifera in places, but is otherwise singularly devoid of organisms. Zuber has aptly compared it with the huge delta deposits of the Orinoco. Rock-salt and mineral oil characterise the Miocene horizons in Galicia, and Dr. Uhlig (p. 864) accepts an unconformity between these and the Karpathian Sandstone. He then shows how the present broken condition of the salt-beds may be due to post-Miocene earth-movements.

The important volcanic zone on the inner side of the mountain-ring raises again (p. 879) the question of the relations of the igneous rocks at Selmeczbánya. Prof. J. W. (not "C. W.") Judd is quoted, and the existence of a great central volcano is left as a possible solution. It is pleasant to find a photograph of the lofty obsidian cliff of Geletnek among others of this picturesque area. The rich ore-deposits of northern Hungary occupy cracks in the Miocene lavas, and are among the latest manifestations of the solfatara stage of the eruptions. While the Mesozoic rocks of the Karpathians were folded in early Eocene times, the volcanic outbreak can only be connected with the slighter post-Miocene movements, and appears to have accompanied the general sinking of the lowland.

We cannot do full justice, in concluding this notice, to Dr. Rudolf Hoernes's section on the plains. The Cainozoic history of the empire is involved in that of these great wind-swept level lands. We are taken from the basin of Vienna, which is really an area of depression formed within the body of the Alps, to the sandy reaches on the edge of the Government of Warsaw, where soil and vegetation have difficulty in clinging to the surface (p. 1049). The salt-beds of Wieliczka (p. 942) again come in for treatment, since the separate publication of the four divisions of the volume renders some overlapping unavoidable.

The ravine of the Danube east of Passau, already touched on picturesquely by Dr. F. E. Suess (p. 105), receives full discussion here after an interval of a thousand pages. Following Penck, the general conclusion is that the Danube flowed in pre-Glacial times over the detrital deposits of late Cainozoic age, cutting broad valleys in these, and ravines where it reached down to the underlying ancient rocks. The present prominence of the latter rocks is due to the denudation of the more yielding Cainozoic strata.

Of the four authors, Dr. F. E. Suess perhaps best realises the landscapes in his word-pictures; but the whole book has a literary value, and is thus all the more competent to stimulate observation and research. Its modernised spelling, such as "Zentralkern" and "Gneise," is perhaps a sign of its virility. The absence of an index will surely soon be rectified.

GRENVILLE A. J. COLE.

A NEW FRENCH TREATISE ON CHEMISTRY.

Traité de Chimie Minérale. Published under the direction of Henri Moissan, with many collaborators. Tome Premier—Métalloïdes; Tome Troisième—Métaux. Pp. xiii+527 and 672. (Paris: Masson et Cie., 1904.) Price 125 francs net.

THE recent advance in inorganic chemistry, to which M. Moissan has in no small degree contributed, has rendered it advisable, in his opinion and in that of his co-workers, to take stock, so that those engaged in research in that branch of chemistry may have in an accessible form an account of the whole field and a full bibliography of published memoirs. It is the laudable ambition of the editor to point out what gaps still remain unfilled, and where research may most profitably be undertaken. The atomic theory is

assumed as a basis of method, but in his preface M. Moissan says :—

"Nous apportons, sur ce sujet, des idées éclectiques, et la raison, éclairée par l'expérience, sera toujours notre seul guide."

The geological and mineralogical sources of substances are considered, but the details of physical and analytical chemistry are not touched. Industrial operations are sometimes chosen to illustrate chemical change, and, where thought desirable, the prices and tables of production of different countries are introduced. The work is primarily intended for those engaged in research, in industry, and in teaching. Among the thirty-two contributors may be mentioned the names of Charpy, Étard, Le Chatelier, Lemoine, Sabatier, and Vogt, besides many others of good reputation.

The introduction by the editor gives a historical sketch of the classification of the elements. In the present state of our knowledge of elementary bodies it is interesting to meet with the unprejudiced words of Lavoisier :—

"If, by the word element, we mean the simple and indivisible molecules of which bodies are composed, it is probable that we do not know them; but if, on the other hand, we apply the name element or principle to the last term at which chemical analysis arrives, all substances which have not hitherto been decomposed are for us elements."

The bearing of spectrum analysis on the question of the unity of matter is briefly touched on, and Moissan says that in his own high temperature work no sign of transmutation has ever been observed. He inclines, however, to the supposition of the unity of matter, and in alluding to the recent work connected with radio-activity, he believes that "we are witnessing the dawn of inorganic chemistry, a subject not long ago regarded as exhausted."

Various attempts at classification are next considered, but not even the periodic table is adopted. The reviewer cannot agree that the method followed presents any advantage whatever. The first family comprises hydrogen and helium, and the reason given for this curious collocation of elements is that helium is not well known! Carbon is separated from silicon, because the latter element forms no large number of "organic" compounds, and because the halides of silicon, like those of titanium and zirconium, are decomposed by water. While in most groups the element of lowest atomic weight is discussed first, cæsium begins the metals of the alkali group, because of its chemical activity; for the same reason the nitrogen group should begin with phosphorus. The final statement that the author thought it better to group the elements in accordance with their known properties rather than to give them to the reader in the disorder of alphabetical order seems hardly a happy way of determining which method of classification is the best, seeing that no particular properties are chosen, the criterion of resemblance sometimes being the appearance of the element, sometimes its melting-point, sometimes the stability of its salts in presence of water, and sometimes none of these, as where cobalt is placed in the same group as uranium, and lead and tin are separated from each other.

The result is, that without an index, which has not yet appeared in any one of the published parts, it is an almost hopeless task to find any desired compound. Gmelin's plan, perhaps, may serve as guide, that is, to find out the elements which have been treated of already, and to take the last in the formula of the compound as an index. But this leads to such an anomaly as having to look up bismuth thiocarbonate under "carbon," while potassium thiocarbonate comes under the heading "potassium." The amido-derivatives, too, are to be found after the salts from which they are prepared, and do not form a group by themselves, similar as they all are to each other.

Subject to these criticisms, however, the work is very complete, and is a most valuable compilation. It is unfortunately not free from omissions; for example, in discussing the determinations of the density of hydrogen, the work of Lord Rayleigh has been overlooked. Again, it is stated on the authority of Lunge (1879) that the greatest amount of chlorine in the world is made at the St. Rollox Works in Glasgow, a statement which is now unfortunately inaccurate. The spelling of proper names, also, leaves room for correction; Brareton-Baker, Tadeusz Estreicher, and Stass are among those which have caught the reviewer's eye. But, as before remarked, the index of literature is very large, and the number of facts given is greater than what is ordinarily to be found in a text-book, while the information is generally up to date, and these are advantages which cannot be overlooked.

ELECTRIC TRAMS.

Electric Traction. By J. H. Rider. Pp. xvi+453. (London: Whittaker and Co., 1903.)

THE name of the author and his position as chief electrical engineer to the London County Council Tramways are sufficient to recommend this book to anyone interested in electric traction. Nor do we think that anyone who takes it up in the hope of gleaning some useful or suggestive information is likely to put it down with the slightest feeling of disappointment. The style is terse, but eminently readable; the opinions expressed by the author are often, no doubt, open to argument, but they have the great merit of conveying the impression that they are the opinions of a man who knows practically all that there is to be known about his subject, and who does not hesitate to state his own convictions, whether they are likely to be in agreement with those of other people or not. For example, we may refer to the little outburst of evident irritation at the need for the objectionable but compulsory guard-wires. These, the author holds, "do not strike at the root of the matter, which is to prohibit entirely uninsulated wires of any kind crossing above the trolley wires." Here speaks not the expert, but the tramway engineer; perhaps if fate had destined Mr. Rider to be a telegraph engineer, we

should have been told that the only thing to do was to prohibit entirely uninsulated wires of any kind from crossing below the telegraph wires. Why should the telegraph wire be banished underground rather than the overhead equipment changed to the conduit system which Mr. Rider has shown us can be so efficient? We fancy the objection which would be made to the change by either party would be the same—that they would prefer the other side to make it and to pay for it.

The ancient recipe for cooking a hare applies with particular force to the design of a system of electric tramways; the motto of the tramway engineer should always be "First catch your passenger." One cannot read this, or, indeed, any comprehensive book on electric traction, without being strongly impressed by the degree to which the whole of the engineering depends ultimately on the halfpenny passenger. The engineer builds a bridge, dams a river or constructs a railway from the Cape to Cairo, and the work is a piece of engineering almost pure and simple, but he may design and equip a first class traction system—generating station, engines, dynamos, cables, track, line and cars—and if he is out of his reckoning as to the time the housewife goes to market all his energy has been wasted. It is she who determines the kind of car and the kind of service, and, these once settled, everything else follows almost as a matter of course. It is here really that electric tramways and electric traction score so heavily; they have the flexibility which enables them to be designed to meet and to satisfy the requirements of the public in a way which cannot be done by the omnibus on the one hand or by the steam railway on the other. The fact that electric traction came into being when these other means of transport were in strong possession of the field has been to its own advantage; it has had to cater for the requirements of the public in a way to attract them from its rivals, and the success with which it has done so is shown by the reaction on the railways, which are one by one resorting to electrification as their only salvation.

Electric tramway and railway development in England has been for a long time retarded from various causes, but of late years it has been making steady progress. Though much has already been done, there is still a vast amount to do. Our large cities all afford transit problems which it is safe to say no other method of traction yet known can solve so satisfactorily, and when these, as socially the more pressing, have been tackled, the question of light railway construction between town and town still offers great fields for development. We have not here the opportunities which the Americans possess but we have problems of our own at once more difficult and more urgent of solution. London in particular is a case in point, and there can be no doubt that once the Royal Commission now sitting has reported electric traction schemes for London will be plentiful. The electrical engineer who decides to go in for traction work is certain before long of great opportunities; he cannot better prepare himself for taking advantage of those opportunities than by reading Mr. Rider's book.

MAURICE SOLOMON.

OUR BOOKSHELF.

Milk, its Production and Uses. With Chapters on Dairy Farming, the Diseases of Cattle, and on the Hygiene and Control of Supplies. By Edward F. Willoughby, M.D. (Lond.), D.P.H. (Lond. and Camb.). Pp. xii+259. (London: Charles Griffin and Co., Ltd., 1903.) Price 6s. net.

ALL medical men and hygienists must necessarily know something about milk and its production, and this work, in a comparatively small compass, deals very fully and adequately with the whole subject. The author, being scientific adviser to one of the largest of the London dairy companies, has had practical experience in all branches of the subject, and his views, therefore, are worthy of confidence. The first four chapters are devoted to a consideration of the various breeds of cows, the qualities of the milk they produce, and their housing, feeding, breeding, and diseases.

In the fifth chapter the legal aspects of diseases of cattle are discussed, and a useful summary of the "Diseases of Animals Acts" and of the "Dairies, Cowsheds and Milk Shops Orders" is given.

The important subjects of the elimination of tubercle and the inspection and control of cowsheds are briefly treated. The physiology and dietetics of milk, pasteurisation and sterilisation, condensed, skimmed, and separated milks, therapeutics of milk, koumiss and other milk preparations, and diseases conveyed by milk, all receive brief attention.

The book concludes with chapters on the dairy, on milk analysis, on control of adulteration, with an abstract of the Foods and Drugs Act, and on the bacteriological examination of milk. The whole work is eminently practical and readable. As regards the conveyance of scarlatina by milk, the well known Hendon outbreak is detailed, but no reference is made to Prof. Crookshank's researches, which throw considerable doubt on some of the conclusions arrived at by the officials of the Local Government Board. The author considers that the alleged tendency to scurvy or scurvy rickets in infants brought up on sterilised milk is not proven, and with this we agree. It is stated (p. 142) that Nuttall and Thierfelder failed to rear young rabbits and fowls brought into the world under aseptic conditions so that their intestinal tracts were free from bacteria. This is not the case; Nuttall and Thierfelder found that guinea-pigs (not rabbits) so reared were even more vigorous than animals reared under ordinary conditions.

The book will prove a useful work of reference, especially for medical officers of health, and the numerous excellent illustrations add considerably to its value.

R. T. HEWLETT.

A Treatise on the Principles and Practice of Dock Engineering. By Brysson Cunningham, Assoc.M.Inst.C.E. Pp. xviii + 559. (London: Charles Griffin and Co., Ltd., 1904.) Price 30s. net.

THE author of this book is on the engineering staff of the Mersey Docks and Harbour Board, which has control over the largest and most efficient system of docks in the world. During the last few years, under the direction of Mr. Lyster, the engineer-in-chief, these docks have been modernised and brought up to date. New deep-water basins and repairing docks have been built; the entrances and sills of some of the old docks have been lowered. Transit sheds and cranes of modern type have been erected, so that these docks are now able to deal with the largest class of vessels yet built, and to load and unload the largest

cargo steamers in the most rapid and efficient manner possible.

Mr. Cunningham has therefore had unrivalled opportunities of acquiring both a theoretical and practical knowledge of dock construction, and in the volume now under notice he has brought together in a concise and well organised form the results of the knowledge thus acquired. The author has not, however, relied solely on his own experience, but has freely made use of the information contained in the numerous papers on dock matters contributed to the *Proceedings* of the Institution of Civil Engineers and to the numerous reports of the International Navigation Congresses and other technical societies. Of these he has evidently been a diligent reader, as few points of interest in the *Proceedings* of the societies or in the technical journals that have been dealt with during the last few years seem to have escaped his notice.

While the study of this book may be regarded as essential to the younger engineers engaged in dock work, it will be invaluable as a book of reference to the expert engaged in this branch of engineering and its cognate interests.

The book is divided into twelve chapters, dealing in an exhaustive manner with the designing and construction of docks, the materials and plant required, the theory of construction of the walls and gates, the equipment and working of docks when constructed, the appliances required for the handling and transport of cargoes to and from the docks, and for repairing the vessels. The book is well illustrated, there being no less than 34 folding plates and 468 illustrations in the text. The book does great credit both to the author and to the publisher, but, of course, the greatest merit belongs to the former for having furnished the dock engineer with such a valuable aid to his work.

Electric Lighting and Power Distribution. Vol. ii. By W. P. Maycock, M.I.E.E. Pp. xxii+684. (London: Whittaker and Co., 1903.) Price 7*s.* 6*d.*

THIS little book covers a very great deal of ground, so that it is hardly necessary to say that no subject is discussed in any great detail. The opening chapters deal with dynamos, alternating currents and alternators, and these are followed by a chapter on electricity meters, in which most of the leading types are described and illustrated. The next chapter deals with motors; a dozen pages in this chapter are all that are devoted to electric tramways and railways, which will give some idea of the amount of consideration which each branch receives. Other chapters deal with batteries, transformers, and generating stations. The treatment throughout is of a very elementary character, but the descriptions are clear and concise, and the illustrations well selected and very clearly reproduced, so that the book should be of service to the student for the City Guilds and similar technological examinations, for whom it is primarily intended.

Builders' Quantities. By Herbert C. Grubb. Pp. viii+227. (London: Methuen and Co., 1904.) Price 4*s.* 6*d.*

THIS book has been prepared more particularly for the use of candidates studying for the examination in builders' quantities held by the City and Guilds of London Institute. The modes of measurement and examples of "taking off" are given in order for the work of all the trades employed in the erection and completion of a building; and these sections are followed by explanations of squaring dimensions, abstracting, and billing. The text is illustrated by seventy-seven figures.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Origin of the Horse.

THE receipt of a copy of Prof. J. C. Ewart's admirable paper on "The Multiple Origin of Horses and Ponies" suggests a few remarks. The paper in question is from the *Transactions* of the Highland and Agricultural Society of Scotland, 1904—one could wish that it had appeared in a publication which comes more regularly under the notice of zoologists. In a previous paper (*Proc.* Roy. Soc. Edinburgh, 1903) Prof. Ewart had shown conclusively that *Equus prjevalskii* was not a hybrid between the kiang and the common horse, and had arrived at the conclusion that it might very well rank as a valid species. Lydekker in 1902 had proposed to regard *E. prjevalskii* (or *przewalskii*) as a subspecies of *E. caballus*, and now Prof. Ewart does the same, while recognising also two other subspecies, *E. c. typicus* and *E. c. celticus*. The animal named *typicus* is the Norse horse, which is arbitrarily selected as the type of the Linnean *caballus*. The Celtic pony, still surviving in the pure state in Iceland, is given the new name *E. c. celticus*. In its way, Prof. Ewart's demonstration of the distinctive characters of this animal deserves to rank with Darwin's treatise on the primrose, as an example of genius applied to common things. The case is so clear that the author himself is evidently half inclined to regard the Celtic pony as a valid species, and it seems to me that the facts justify us in recognising three species of living horses, *E. prjevalskii* (Poliakoff), *E. celticus* (Ewart) and *E. caballus* (L.). The indications are that these animals were quite distinct in the wild state, and the fact that various blends between *caballus* and *celticus* exist in domestication is no more proof of specific identity than the same sort of thing is among the dogs, which nobody doubts to have originated from more than one wild species.

The use Prof. Ewart makes of the prehistoric cave drawings of horses is most suggestive. Possibly these sketches may have been taken a little too seriously in some instances, too little allowance being made for eccentricities in drawing. Fig. 27, from the Kesserloch cave, has a remarkably long body, and one might joyfully recognise the *Equus scotti*, Gidley, were it not that that animal inhabited the plains of Texas and New Mexico.[1] Prof. Ewart accepts the opinion that the living American horses are wholly of Transatlantic origin. While this is probably correct, I was surprised on looking into the matter a few years ago to find that the evidence was not so complete as I had supposed. It is said that the natives showed great surprise at the horses of the Spaniards, being evidently unacquainted with the animals. This was to be expected, for if wild horses lived in America at the time of Columbus, they surely were not in the "tierra caliente," but rather to the

[1] The New Mexico record is based on a molar tooth found by Miss Ada Springer in the Pleistocene beds of the Arroyo Pecos, Las Vegas, and examined by the writer It differed in no respect from Gidley's description and figure. Mr. Gidley kindly made for me a number of skull-measurements from the types of *E. scotti*, and I found upon comparisons that the five specimens were much more uniform than a similar series of *E. caballus* picked at random would be. This may be attributed no doubt to the greater uniformity of the wild species, but also to these particular specimens being apparently (from the circumstances of their discovery) members of the same herd. The skulls were 571 to 590 mm. long, and differed from any *caballus* of which I had measurements in (1) the rather longer muzzle, with the upper dental series (molars and premolars) considerably longer, 195 to 204 mm., and (2) apparently in the greater breadth between the orbits above, but Mr. Gidley afterwards wrote that he found that while the breadth between the *anterior* borders of the orbits of *scotti* is slightly greater than in large skulls of *caballus*, the breadth between the *posterior* borders is less; hence it would seem that the eyes of *scotti* looked less forward than those of *caballus*. The other measurements:—zygomatic breadth, greatest breadth of muzzle, least breadth of palate, distance between molars of opposite sides, and the greatest breadth of posterior nares, all fall within the limits of variation of *E. caballus*. Hence it is apparent that *E. scotti* was in many respects similar to *caballus*, as Mr. Gidley indicated in his paper on the subject. The bones other than the skull, taken separately, could not be distinguished from those of *caballus*. Other differences in the skulls than those mentioned have been fully described and illustrated by Mr. Gidley, and the facts need not be repeated. No doubt a more minute study of the osteological characters of fossil horses would throw valuable light on the significance of variations in the living forms.

north, in the region of the prairies. Moreover, even if the natives had known the horse, they might well have been astonished at the horse-and-man combination.[1] Then it is difficult to understand why Equus became totally extinct, since subsequent events showed that vast areas were admirably adapted to it. Prof. Ewart informed me (*litt.* 1902) that the Chinese were alleged to have visited America about the eleventh century, and reported it as the "land of women, the horse and the vine." This tradition is apparently not to be regarded very seriously, but the antiquity of the genuine *Equus caballus* in North America is supported by O. P. Hay in his excellent catalogue of the fossil Vertebrata of North America (1902), p. 622. This author boldly lists *E. caballus* as Pleistocene on this continent, and while admitting that "in some cases the identifications have been open to question," and "in other cases the remains may have been derived from the introduced race," he adds, "the former existence of the species in Alaska and in California appears well established." Of course, the term *E. caballus* must here be understood in the wider sense. Prof. Ewart also remarked, in the letter just cited, that the Spaniards at the time of the conquest used small-headed horses, "the offspring of the *E. fossilis* of Asia in all probability," whereas the characteristic "buckskin" pony of our south-west is a relatively large-headed animal. Furthermore, Mr. Wilfred Blunt, through my brother, Mr. S. C. Cockerell, communicated the statement that "the Spaniards never rode mares, and can hardly have brought any but stallions with them in their ships to their colonies." Hence the early abundance of wild horses in North and South America appears very remarkable. With reference to the presumed early absence of horses, one may also remark that so common an animal as the "antelope" (Antilocapra) was not made known to naturalists until about 1815, and a perfectly new wild sheep was discovered in northern Mexico in 1901! Even the known variability in colour of the wild horses might be thought of as a Mendelian phenomenon, resulting from the mixture of different types, and the infusion of new blood could be conceived to have resulted in greater vigour and consequent increase in numbers.

T. D. A. Cockerell.

Colorado Springs, Colorado, U.S.A.

This paper, only slightly abridged and with about one-third of the figures, appeared in Nature of April 21 (vol. lxix. p. 590). I am more than "half inclined to regard the Celtic pony as a valid species" and to recognise three species of living horses. I prefer, however, to leave systematists to decide whether Prjevalsky's horse and the Celtic pony should be regarded as species or merely as varieties.

J. C. E.

Entropy.

An author expects some unfavourable reviews, and, if wise, profits largely by them; but Prof. Perry's review of "Entropy" in Nature of April 14 is simply an attempt to brush away a book the object of which is to eradicate what, I submit, is a very widespread mistake, because the reviewer has himself not only made the mistake, if mistake it be, but championed it. This mistake is that entropy is conservative in irreversible change; that the entropy of a body is increased only by its taking in heat, or that $\int dH/\theta$ is the entropy in irreversible change; or that dH/θ is a complete differential. In Prof. Perry's own words, "There is a property of the stuff called its entropy ϕ, which is such that any change in it, $\delta\phi$ if multiplied by t the absolute temperature gives δH or $\delta H = t\delta\phi$." "ϕ is to heat re-received H something like what v is to work w." "If we divide every δH by t, . . . every amount δH being divided by the t at the time, and if we call δH divided by the t by the name, entropy, we shall find that when the stuff is brought back to its old state again, we have just given out as much entropy as we have taken in. The account balances exactly."

In a note to a presidential address I pointed out that such statements are numerically correct in reversible changes only, that in all irreversible changes they are not accurate, and that they thus give a wholly wrong idea of the function entropy. There was no question, and never has been, about reversible changes, that is to say, changes where p and θ are uniform throughout the working substance; the whole of my criticism refers to irreversible changes alone.

Prof. Perry then started a correspondence in which Prof. Poincaré and Prof. Planck were good enough to join, and also showed how Prof. Perry was wrong (*Electrician*, March 13, 1903). I quote from Prof. Planck's letter:—

"The controversy excites my attention the more, when, to my astonishment, I see a man so well known and so eminent in science as Sir Oliver Lodge[1] putting forward ideas on thermodynamics (*Electrician*, January 23, p. 460) which I combated ever since the commencement of my studies in that science."

"But how can I hope with my words to make any impression on such writers when Mr. Swinburne's excellent articles have failed to effect any change in their preconceived ideas? For, with one reservation,[2] what he has written in the *Electrical Review* (January 9, p. 52) is, in my opinion, one of the best and clearest expositions of the subject that has ever been written, especially where he points out that Nature never undertakes any change unless her interests are served by an increase of entropy, while man endeavours so to make use of those changes allowed by Nature that his own interests—namely, the acquisition of available energy—are served as completely as possible."

Science can never be a matter of authority, but I quote Prof. Planck because Prof. Perry now reviews the book as if his definition of entropy was universally accepted in thermodynamics, and adopts the tone that anyone who differs from himself and develops Clausius's inequality, $\int dH/\theta < \phi$ for all irreversible changes, is wrong *prima facie*.

Though the review contains quotations from the little book, they are always incomplete, so as to give as far as possible an absurd meaning. Thus the quotations about errors in text-books look as if I said text-books on thermodynamics are wrong. What I do say is that books on physics and steam engines define ϕ as $\int dH/\theta$, whereas books on thermodynamics show that is accurate for reversible changes only. The whole gist of my book is the application of Clausius's principle of increase of entropy. Books on steam engines, and generally on physics, as opposed to those on thermodynamics, say $d\phi = dH/\theta$, and dH/θ is a complete differential. If θ means the temperature of the working substance when that temperature is not uniform, dH/θ has no meaning, and is not a complete differential. By θ in irreversible change, as I have often explained, I mean the temperature at the separating surface through which dH passes. If no meaning can be given to dH/θ in irreversible change, my criticism that dH/θ is not a complete differential, except in the ideal case of reversibility, is still valid. "It is hardly believable that in a dynamical illustration he should imagine the momentum of a system of two colliding bodies to be increased by the collision" is calculated to give the impression that I am ignorant of elementary mechanics. The context is discussing the sum of the scalar momenta of gas particles. This increases when some isolated gas equalises its temperature at constant volume. "But as we have the foot-pound,

[1] Some of the aboriginal pictographs show horses, but these are apparently of recent date. Unfortunately we have no ancient American drawings of animals comparable to those of Europe.

[1] The reference to Sir Oliver Lodge occurs because he wrote an article on entropy defined so that $H = \int \theta d\phi$, which I take it he has recalled. It was because I thought the weight of his authority might tell harmfully that I sent the correspondence to two leading authorities on thermodynamics.

[2] This was my statement that $d\phi$ is never a complete differential in irreversible change. For $d\phi$ to be a complete differential in terms of, say, $d\theta$, dv, we must have $d\phi = Md\theta + Ndv$, where $\partial M/\partial v = \partial N/\partial\theta$. To prove $d\phi$ a perfect differential during any irreversible change the equation must be true while the change is going on. It is not accurate to put the value of θ or of p which obtained before the change started, or would be reached if the change were arrested and the substance allowed to come to uniform temperature and pressure. Prof. Planck is so much better a physicist and mathematician than I am that I do not contradict such an authority; I merely say there is a misunderstanding, which may be mine, and I submit my contention. My view is that the physical meaning of a complete differential in mechanics is not only that the integral is completely determined by the coordinates, but that it is conservative. Lagrange's treatment of mechanics really involved the conservation of energy, that is to say of the forms he discussed.

and I think the poundal, as units of energy" looks as if I confuse force and energy. The context shows that I object to non-metric units as unscientific, and therefore do not care which unit bears the name poundal. The statement that I want to have Claus instead of Rank for the British unit of entropy is wrong. The claus is the unit of entropy in the practical metric system where the joule is the unit of energy. The rank is a name proposed by Prof. Perry for $\int dH/\theta$, and as this is not entropy in any real change, I cannot adopt it as a unit of entropy. As to $d\chi$, I will deal with that elsewhere; it is a side issue. The statement that I talk of "the entropy of a quantity of heat" is wrong. Prof. Perry holds that entropy is a factor of heat. I dissent, and agree with Prof. Planck that entropy is not a factor of energy. So far from talking of the entropy of a quantity of heat, I have explained very fully how and why entropy is in no sense a factor of heat.

I would not write were a review in NATURE not particularly important, and I trust you will, in fairness to my publishers and myself, allow this letter to appear.

41 Palace Court, W., May 1. JAMES SWINBURNE.

MY sole object in the controversy to which Mr. Swinburne refers was to show that, like most of the other writers of whom he complained, I have never either made or championed the mistakes he speaks of at the beginning of this letter. As to my notice of his book, I cannot admit that I have misrepresented him except as to the *claus*. I made a mistake in saying that his claus is what is sometimes called a *rank*. As he now says that the momentum of which he spoke was a *scalar* momentum, I submit that I was quite fair in my comments. I cannot admit that his $\theta\chi$ diagram is a side issue. JOHN PERRY.

Origin of Plants Common to Europe and America.

THAT there is a resemblance between the floras of Canada and northern Europe, and again between the floras of Canada and of eastern Siberia and Japan, is well known. Including the horsetails and ferns with the flowering plants, probably about 575 species are identical in Canada and Europe, and again about 330 in Canada and Japan or the River Amur country. A large number of these are common to the three continents. The hypothesis generally accepted has been that, in some comparatively recent epochs, there has been a connection between Europe and America which facilitated the intermingling of the plant life of the two continents. The late Prof. Asa Gray suggested the probability that the migration of European plants had taken place across Asia to America. Lesquereux, from his studies of the flora of the Dakota group, on the other hand, maintained that the North American flora is not now, nor has it been in past geological ages, the result of migration, but that it is indigenous. It has long been known that species now extinct occurring in the Miocene of Europe had appeared in America at an earlier period. Lester Ward enumerates eleven species—all now extinct—as common to the Laramie group in the United States and the Eocene of Europe, and shows further that at least two living species now found in both Japan and America date their origin in America as far back as the Eocene. Twenty years ago my own studies in the distribution of Canadian plants also convinced me that whilst facilities had existed for migration in both an easterly and a westerly direction, Canada was the point of origin of many of the species now identical in Europe and America. This conviction has been heightened by further knowledge of the range in Canada of these identical species and by further discoveries during recent years of plants in the Pleistocene clays of Canada. Of seventy fossil species in these Pleistocene clays at Toronto, Ottawa and elsewhere, twenty occur at the present day in both Europe and Canada, fourteen are similarly Asiatic and Canadian, whilst eleven are common to the three continents. This, if it does not necessarily indicate that in Pleistocene times the intermingling of these floras had already been effected, at least shows that in this period these identical species were present in Canada, and had here their place of origin if there is nothing to indicate their presence at as early a period in Europe or Asia. In its vast areas of exposed Laurentian and Huronian formations, Canada has an old look about it, and must have furnished a home through long past ages for the growth and diffusion of northern temperate plant life, when other sections of the globe have from time to time been under water.

The peculiarities of the present range over Canada of many of these identical species also afford suggestions. Whilst many of them are distributed somewhat generally over the country, and many are high northern or Arctic, quite a number do not range west of Lake Superior; others have not been found west of the Rocky Mountains, whilst some are confined to British Columbia and Alaska. In view of their occurrence also in either Asia or Europe, this circumscribed range of so many species suggests their antiquity, and that the elevation of that lofty barrier, the Rocky Mountains, and the disturbance of the relations of land and water in Manitoba and the North-West Territories in more recent times, has resulted in these plants being confined to their present range where forest conditions were more suitable, and has led to the treeless prairies and plains being tenanted by new groups of species specially suited to the new conditions there, when the land rose to its existing level. A. T. DRUMMOND.

Toronto, April.

Moisture in the Atmosphere of Mars.

IN your issue of May 5 I see a note in the astronomical column on Mr. Lowell's theory of the Martian canals. It is perhaps not just to criticise it on so short a summary, but there is a point on which I should like to ask a question. If, as Mr. Lowell says, there is not sufficient moisture on the planet to produce vegetation, how does the water return to the poles ready for the next summer? The only way, it seems to me, is by evaporation. His suggestion of artificial waterways to carry the water from the polar caps implies the existence of an atmosphere sufficiently dense to enable intelligent beings to live. That being so, is it not just as plausible that the evaporated water should condense in the form of rain on the general body of the planet as well as at the poles? although, of course, the excessive cold would account for an increased fall at these extremities.

Bournemouth, May 10. ARTHUR J. HAWKES.

Radium and Milk.

IN the souring of milk the amount of lactic acid developed may reach 0·80 per cent. in three or four days when the milk solidifies. In view of Sir O. Lodge's suggestion (NATURE, October 1, 1903), I have made experiments comparing the rate of acidification, in two to three days, with and without the influence of radium rays from a 5 mgrm. radium bromide tube. The differences in five cases did not exceed the limit of experimental error, 0·01 per cent. of lactic acid, and in a sixth case with the milk solidified the difference only amounted to 0·05 per cent. of lactic acid. It therefore appears to me that under normal conditions radium rays have little or no effect on the functions of the lactic acid bacillus. WILLIAM ACKROYD.

Halifax.

THE BANTU RACES OF SOUTH AFRICA.[1]

NOTHING so good as this book dealing with the Negro indigenes of southern Africa has yet appeared. Mr. Dudley Kidd's work is therefore entitled to take the first rank on this subject, at any rate as far as the Bantu races of South Africa are concerned.

It is a national humiliation to us to reflect that as a Government we have been connected with South Africa for more than a century, that is to say, two-thirds as long as our imperial connection with India has lasted, and yet that by Government endeavour or

[1] "The Essential Kafir." By Dudley Kidd. Pp. xiii+436. (London A. and C. Black, 1904.) Price 18s. net.

private research so little of value has been published in the English language on the native human races of Africa south of the Zambezi. The present reviewer does not overlook the excellent but incomplete work of the late Dr. Bleek, of Sir George Grey and of McCall Theall, nor should the short work by Theophilus Hahn on the Supreme Being of the Hottentots be left unmentioned. The author of the work under review is also right in calling attention to the value of the Rev. Canon Callaway's work, published in the 'sixties of the last century on the religious system of the Zulus; and the writings of the French Protestant missionary Casalis on the Basuto and Bechuana languages should not be left unrecorded.

The author gives at the end of his book, "The Essential Kafir," a bibliography of the works written in English and French on the Hottentot, Bushmen and Bantu races of Southern Africa. He has omitted to include a variety of books in the German language on the Damara (Ova-herero) people and language. But these (which are by no means final, comprehensive, or even particularly valuable) have owed nothing in their inception to the British rule over South Africa. Consequently the slur still remains, especially when we compare such a list as is given in the Appendix to "The Essential Kafir," with a list which might be compiled of works on the native races and languages of India, or even of British Central Africa. It is difficult to understand why scientific Anthropology has played so poor a part in British South Africa; but no doubt it is due to the fact that the great personages, appointed or self-made, who have ruled over or have influenced South Africa during the last hundred years, never, with the exception of Sir George Grey, took the slightest interest in these questions, or cared to enlighten themselves or others on the characteristics of the native races whose doings or misdoings were provocative of so much bloodshed and expenditure of money.

Even those who have left on record their studies of the Negro races in South Africa—with the exception of Dr. Bleek seem to have carried on those studies with little or no reference to the lands beyond the Zambezi. Many South Africans fancy that the linguistic term Bantu, which was first coined by Dr. Bleek, applies wholly to the Zulu-Kafir-Bechuana peoples of the South African Colonies, and do not realise that it was intended by Dr. Bleek, and has since been used, to cover nearly all that section of the Negro race which inhabits the southern half of Africa between the northern limits of the Congo basin and the Equatorial Lake regions and the eastern districts of Cape Colony.[1]

FIG. 1.—A Swazie making Fire by Friction. From "The Essential Kafir," by Dudley Kidd

Consciously or unconsciously, Mr. Kidd in the book under review brings out emphatically the "Central African" characteristics of the Zulu-Kafir people. (It would be a good thing for consistency of speech if we induced the world at large to drop the term "Kafir," and to apply some such name as Zulu to all those Bantu tribes in South Africa—as apart from the Bechuana, the Herero, and the Zambezi people—which speak dialects of the Zulu language. Kafir—originally spelt Caffre—was the Portuguese rendering of the Arabic "Kafir," plural "Kufar," which means "infidel" or a race not believing in Islam. When the Portuguese vessels first rounded the Cape

[1] Dr. Bleek's use of "Bantu" was more connected with linguistic classifications. Whether there is a negro physical type which is connected with the making of this distinct group of languages is still undetermined; Dr. F. Shrubsall, the anthropologist, thinks there is.

of Good Hope and touched at the coast of south-east Africa, they found Arabs or Arab half-castes trading there, and learning that these called the black natives of the country "Kafirs," they adopted this term henceforth as the designation of the Bantu coast races of southern Africa, and passed on this word to the Dutch, who handed it over to the English. Mr. Kidd, by his excellent and detailed description of Kafir customs, myths, folklore, songs, dances, and implements, shows how inseparable these people are in classification from the Negro races of tropical Africa. This deduction is in varying degrees affected by an examination of South African Bantu languages. Of this subject Mr. Kidd does not treat at any length, but it might be mentioned that a careful study of such linguistic works as those of the late Dr. Bleek brings out the following points:—

A study of the existing languages of the Ova-herero of south-west Africa, of the many Bechuana tribes of central South Africa, and the languages of the Zulu-Kafirs from Cape Colony on the west and south to the Portuguese district of Inhambane (Nyambane) shows that there is fundamentally a common though remote parentage to these languages so far as the vocabulary and grammatical structure are concerned; that is to say, that there is more evidence of inter-relationship between these three groups than there is between any one of them and the Bantu languages to the north and north-east. But there are still very striking differences in phonology between the Herero, Bechuana, and Zulu groups, showing that the history and wanderings of each section must have differed considerably. The Bechuana languages are the most altered from the original Bantu structure, but they are without the clicks which seem to give a Hottentot aspect to the Zulu dialects, and I believe that very little that is Hottentot can be traced in the etymology of the Bechuana vocabulary. But the phonology of this language is so peculiar as to suggest its great isolation at one period from other Bantu dialects. Some students of Bantu languages, however, have thought that the Bechuana races may have been the pioneers of the Bantu invasion into the regions across the Zambezi.

Physically speaking, the various sections of the Bechuana people exhibit far more traces of intermixture with the Hottentot-Bushmen type than is shown by the Zulu-Kafirs or by the real Herero (Damara) people.[1] The languages of the Herero group, though they possess marked characteristics in phonology, are of a very pure Bantu type, and gradually link up northwards with the languages of the Congo coast and with the Bantu speech of the southern portions of the Congo basin. The Zulu language retains some primitive characteristics in the form of the prefixes, which have been changed or lost in the Bechuana or Herero groups. Yet in other respects the Zulu dialects have departed widely from the Bantu standard, especially in vocabulary. This language group is a curious mixture of archaic Bantu features and inexplicable elements which, if not "Non-Bantu," cannot be definitely traced to any known Bantu group of tongues. In a few cases words of this description are of Hottentot origin, but this does not explain many of them, which would appear to have been absolutely invented by the Zulu people, no doubt owing to that strange custom (by no means unknown elsewhere in Africa), of "hlonipa," by which a constant local change of vocabulary takes place owing to the dislike to mentioning names of things which resemble the names of relatives; so that if there be a prominent person in the tribe, for instance, whose name is actually equivalent to "ox," or even whose name sounds like the word for ox, in that village or community the ox will henceforth be known by a paraphrase or by a substituted word.

[1] Except of course the Hill Damaras, who are a mysterious tribe of mountain people in the northern parts of German South-west Africa—a black race similar in appearance to some of the more degraded Negro tribes of West Africa, but speaking a corrupt dialect of Hottentot.

In many respects—as Mr. Kidd's work shows over and over again—the Zulu-Kafir race would seem to have been the last arrived of the Bantu peoples in southern Africa, and to have reached that part of the continent at no very remote period—possibly not more than 1,500 to 2,000 years ago. In some of their characteristics the Zulus irresistibly recall the manners and customs of such Nilotic-Negro races as the Masai, though there is absolutely no linguistic connection between the two peoples. No doubt this can be explained by assuming that the original Bantu group from which the Zulu sprang had sent several previous branches to invade South Africa, which may have been the originators of some of the Zambezi tribes, of the Bechuana and the Herero, and that in this original home, somewhere up in east-central Africa, the Zulu peoples came into contact with Nilotic-Negro races from whom they borrowed customs, arms, and methods of warfare, and with whom they shared religious beliefs. When the Zulus started forth on their southward migration their progress seems to have been a relatively rapid one. We need not be astonished at this when we reflect on the remarkable speed with which a small section of the Zulu people in the first decades of the nineteenth century rushed back into Central Africa, reaching in their raids and settlements even the vicinity of the Victoria Nyanza.

The author has much to say of interest on the vexed question of the clicks in Zulu. There are three clicks in this Bantu language—the only Bantu form of speech which possesses these sounds. Some have considered that they were borrowed from the Hottentot, but of late there has been a tendency on the part of students like Mr. Dudley Kidd and Miss A. Werner to argue that these modern clicks in Zulu have been separately developed without Hottentot parentage. Mr. Kidd points out that at the present day the clicks subsist far more in the language of the women than in that of the men. It should be noted that amongst the settlements of Zulus in east-central Africa, which are about seventy years old, the clicks are rapidly disappearing. Dr. Bleek pointed out in his linguistic studies that certain strong intercalated aspirates met with in Swahili, and in one or two other East African Bantu dialects were not dissimilar to a vanishing click.

The space at my disposal does not permit of my dealing further with the interesting problems raised by this book, which, however, I must repeat, is perhaps quite the best that has yet been written or compiled about the Bantu negroes of South Africa. The hundred plates that illustrate this book are all photographs of perfect execution and singular aptness.

H. H. Johnston.

PROF. E. J. MAREY.

Of the two veteran Frenchmen who entered on their careers as physiological discoverers half a century ago, Marey and Chauveau, the first has left us. The second is in full vigour and is at this moment engaged in active laboratory work.

Marey died on Sunday night after an illness of much suffering. His earliest investigations had for their purpose the devising of methods by which the arterial pulsations could be made to inscribe themselves on an equably moving surface so as to obtain a graphic record from which their time-relations could be determined. One of the earliest products of these

methods was the invention of the sphygmograph, of which the original form (1863) has not undergone any important modification. From the arteries he proceeded to the heart, and for this associated himself with Chauveau, with whom his early friendship persisted unbroken to the end. It was to this association of two able men, one of whom was at that time the most skilful of living experimenters, while the other possessed an equally exceptional faculty of mechanical invention, that we may attribute the splendid researches on which our present knowledge of the motion of the heart is founded.

The results of these investigations were communicated to the Academy of Sciences in the early 'sixties, and soon after published in Marey's first book ("Physiologie Médicale de la Circulation du Sang") in 1863. This work was followed by others, of which were the "Travaux du Laboratoire," published annually by M. Marey after he had succeeded Bernard as professor in the Collège de France. In these he completed the development of the "graphic method" in its relation to the circulation, and extended its application to other bodily movements, particularly to those of locomotion, including the flight of birds. It thus happens that the "kinematographic" method, which in later times has not only been vulgarised for public entertainment, but has served a higher purpose as a guide in the artistic representation of animal motion, was in the first instance devised by Marey for the purpose of physiological research.

It would be difficult to over-estimate the value of Marey's work to the science to which, for the last half-century, he has devoted himself. Full of original ideas and fruitful in resources for carrying them into effect, his ingenious methods have not only served his own purposes, but have been made available by other workers in all investigations relating to the mechanical functions of the animal body. It would be difficult to find a single instance of a research in the carrying out of which these methods have not been employed.

PROF. WILHELM HIS.

PROF. WILHELM HIS, whose death was announced from Leipzig on May 1, at the age of seventy-three, altered and extended our knowledge of human anatomy more than any man of his time. He discovered and wrote the history of the human body during the first and second months of conception, and thus filled in what, until his time, was almost a blank. He introduced more accurate methods of studying the form and relationships of the various organs of the body. Pupils went to him from all parts of the earth and carried back to their native universities the quiet, honest spirit of investigation, the complete methods and the accurate technique His had introduced in his laboratory at Leipzig. His influence to-day is world-wide; it is especially evident in the remarkable progress in embryological research made recently in the United States.

As His entered to lecture one was struck by the absence of those bodily features one expects in a German professor. He was a Swiss by birth and education, having been born at Basel in 1831; in appearance he might have been an Englishman. His narrow, longish head, black hair, regular profile, long sallow face, and nervous temperament indicated his descent from a Celtic stock. He taught quietly, clearly, and concisely, illustrating his subject as he spoke by marvellous drawing on the blackboard. He relegated lady-students to the back-bench. Long after the university doors were shut, a light could be seen in the window of his private room, for to him work was also amusement.

His career as a medical student is interesting. It began at the University of Basel when he was eighteen, and finished there in 1854 when he was in his twenty-third year, but during that period he visited and worked at the Universities of Bern, Berlin, Würzburg, Vienna, and Prague, selecting what was best at each place. After graduating he studied in Paris. In 1857, then twenty-six, he succeeded Meissner as professor of anatomy and physiology in Basel, and commenced his life's work.

It is always a matter of the utmost interest to know the circumstances that determine the direction of a successful line of research. His, in his student days, while working at Würzburg with Virchow, then a young enthusiast, commenced and afterwards finished an investigation into the structure of the cornea of the eye, and in the early years of his professorship published, with Billroth, a research into the structure of lymphatic glands and allied bodies. A lecture which he heard Remak give in Berlin on the developments of glands was really the starting point of his embryological work. The point which struck him as marvellous was the development of a gland such as the liver from two of the three primary layers of the embryo. He commenced to investigate the origin and the part which each of these three primary layers played (ectoderm, mesoderm, and hypoderm) in the development of each part of the body, first in fowls and lower vertebrates, and subsequently in the then almost unknown early human embryo.

Every advance in science rests on the introduction of a new method. By the methods he employed His succeeded where other men had failed. The early human embryo is minute and jelly like; it has to be hardened and stained before it can be cut in microscopic sections; it has to be stained to differentiate its various constituent layers; it has to be cut with a mathematical regularity in order that each section may be magnified and modelled in wax so that, by placing these wax magnifications together, a reconstruction of the embryo may be obtained. Although His did not invent any one of these details, yet he improved each of them and applied them to the study of embryos with an accuracy that never has and never will be surpassed. Duplicates of the models thus constructed are to be seen in all anatomical museums, and are of the greatest service to those who teach as well as to those who pursue embryological research.

The work of Prof. His is not marked by brilliant generalisations or discoveries, nor can his outlook on the kingdom of living things be said to be a wide one. He represented most realistically what he saw, but his power of interpreting embryological facts was limited by his neglect of comparative anatomy. Perhaps the greatest of his discoveries was the manner in which nerve fibres are developed. He was the first to see that they were processes produced by nerve cells. If his limitations are mentioned, it must also be admitted that most of what we know of the early development of all the systems of the human body we owe to him.

Ludwig, who made Leipzig the Mecca of physiologists, early recognised the ability of the young Swiss anatomist, and was instrumental, in 1872, in having him appointed director and professor of anatomy in the University of Leipzig. During the thirty-two years he laboured there, the younger anatomists flocked to him, and by placing his time, advice, and encouragement freely at their disposal, he rendered them deeply his debtors.

NOTES.

In connection with the assembly of the International Association of Academies next week, the international council of the International Catalogue of Scientific Literature will also meet. The following are the members of this council, and the countries they represent:—Prof. H. E. Armstrong, F.R.S., Great Britain; Prof. H. Poincaré and Dr. J. Deniker, France; Dr. W. T. Blanford, F.R.S., India; Dr. M. Knudsen, Denmark; Prof. R. Nasini, Italy; Captain H. J. Lyons, R.E., Egypt; Prof. A. Famintzin, Russia; Prof. Dr. Karl von Than, Hungary; Dr. J. Brunchorst, Norway; Monsieur D. G. Métaxas, Greece; Prof. Dr. D. J. Korteweg, Holland; and Prof. A. Liversidge, New South Wales.

The Weights and Measures (Metric System) Bill was read a third time in the House of Lords on Tuesday, and was passed with various amendments proposed by the public departments to the Select Committee to which the Bill was referred.

Sir William Ramsay has just been elected an honorary member of the "Bunsen Gesellschaft."

Prof. G. H. Darwin, F.R.S., has been elected a foreign associate of the U.S. National Academy of Sciences.

We regret to see the announcement of the death of Prof. G. J. Allman, F.R.S., for more than forty years professor of mathematics in Queen's College, Galway.

The council of the Geological Society of London has this year awarded the Daniel Pidgeon fund to Mr. Linsdall Richardson, of Cheltenham.

The *Times* correspondent at St. John's, Newfoundland, states that Lieut. Peary is chartering the sealer *Eagle* for a cruise to Littleton Island, from July to September, in preparation for a four years' stay in the Arctic regions, beginning next season.

A mathematical society of Vienna has been organised, the meetings of which are to be held monthly. The officers are Messrs. G. von Escherich (president), E. Müller and W. Wirtinger (vice-presidents), A. Lampa (secretary), and A. Gerstel (treasurer).

A fund has been started by the Faculty of Sciences and the Engineering School of Rome with the object of raising some kind of memorial to the late Prof. Cremona. The secretary is Signor I. Sonzogno, 5 Piazza San-Pietro in Vincoli, Rome.

The Royal Academy of Sciences of Madrid offers for 1905 a prize for the best essay written in Spanish or Latin on the following subject:—"A complete study of a special class of singular integrals arising from differential equations for which the values of the derived functions become indeterminate when certain relations exist between the simultaneous values of the principal variables."

Further particulars have been recently issued regarding the mathematical congress which, as announced last summer in Nature, is to take place at Heidelberg from August 8 to 13. There will be six sections, and in addition five conferences presided over by Profs. Wirtinger, Greenhill, Darboux, Segre and Königsberger. It is proposed to hold exhibitions of mathematical models and of mathematical books.

A series of prizes is offered by the mathematical and natural science section of the "Jablonow" Society of Leipzig for themes connected with the following subjects:—For 1904, the chemical differentiation of rock magmas; for 1905, the causes of plasmic currents in vegetable cells; for 1906, the analogues of Bernouilli's numbers in the study of elliptic functions; and for 1907, the laws of photoelectric currents. Full particulars are obtainable from the secretary, Prof. Wilhelm Scheibner, 8 Schletterstrasse, Leipzig.

A brief notice of the late Edmund Hess, who died at Heidelberg on December 24, 1903, is given in a note in *L'Enseignement mathematique*, vi., 2. Hess was born at Marburg on February 17, 1843, and studied mathematics there from 1860 to 1862. The next year he went to Heidelberg, where he studied under Hesse, from whom he acquired his taste for geometry. He subsequently occupied the post of assistant at the Observatory of Göttingen, and in 1866 returned to Marburg, where he held office at first as extraordinary and later as ordinary professor. His papers deal exclusively with geometry, the subjects including "theory of the division of the sphere" and "contributions to the theory of configurations in space."

The ninth annual congress of the South-Eastern Union of Scientific Societies will be held at Maidstone on June 9–11. Mr. F. W. Rudler, the president-elect, will deliver an address on the evening of June 9, and papers will be read on the mornings of June 10 and June 11. There will be several excursions to places of interest to naturalists and archæologists. The hon. general secretary is Mr. G. Abbot, 33 Upper Grosvenor Road, Tunbridge Wells.

On Tuesday next, May 24, Mr. H. F. Newall will begin a course of two lectures at the Royal Institution on the solar corona; on Thursday, May 26, Mr. H. G. Wells will deliver the first of two lectures on literature and the State; and on Saturday, May 28, Sir Martin Conway will begin a course of two lectures on Spitsbergen in the seventeenth century. The Friday evening discourse on May 27 will be delivered by the Prince of Monaco on the progress of oceanography, and on June 3 by Prof. Svante Arrhenius on the development of the theory of electrolytic dissociation.

A correspondent directs our attention to a singular mistake of dates in Mr. Herbert Spencer's "Autobiography." Referring to his visit to Montreal in 1882, Mr. Spencer states (vol. ii. p. 392):—"The meeting of the British Association had ended before our arrival." The meeting of the British Association in Montreal was in 1884, so this was probably a meeting of the American Association for the Advancement of Science which Spencer refers to. This conjecture appears to be confirmed on p. 384, where in a letter to Prof. Youmans he refers to the possibility of attending the meeting of the association at Montreal and supporting Prof. Youmans in his position of chairman of the Committee of Science Teaching.

During the anniversary meeting of the Royal Geographical Society on Monday, the Royal medals for the encouragement of geographical science and discovery were presented; the Founder's medal to Sir Harry H. Johnston, for his explorations and investigations in Africa, and the Patron's medal to Commander Robert F. Scott, R.N., for his conduct of the National Antarctic Expedition, and especially for his sledge journey to 82° 17′ S. The following other awards were also made:—the Murchison grant for 1904 to Lieut. Colbeck, for his services to the society while in command of the relief expeditions; the Cuthbert Peek grant for 1904 to Don Juan Villalta, for important geographical dis-

coveries to the east of the Andes, while in command of a Peruvian exploring expedition; the Gill memorial for 1904 to Captain Irizar, Argentine Navy, for his very successful expedition for the rescue of the Nordenskjöld Antarctic Expedition; the Back grant for 1904 to Dr. M. A. Stein, for his valuable geographical work in Central Asia, and especially for his mapping in the Sarikol and Kwen-Lun ranges.

The Russian papers report that a rather severe shock of earthquake occurred at Shemakha (Caucasus) on April 28 at 6.30 p.m.

A new expedition, under M. Tolmachoff, is being organised by the Russian Geographical Society for the exploration of the region between the mouths of the Yenisei and the Lena.

Records obtained by observers in several parts of the world suggest that an appreciable general diminution of the transparency of the earth's atmosphere took place some time during the year 1902, but disappeared at some time during 1903. As this is an important matter and may possibly be made the basis of an explanation of other meteorological phenomena, Prof. Cleveland Abbe, U.S. Department of Agriculture (Weather Bureau), Washington, D.C., asks observers to send him any records that will assist in defining the dates of beginning and ending, and the extent of this change in transparency. Such records may consist of photometric or photographic observations of the brightness of the stars, changes in the solar or stellar spectra, unusual prevalence of halos, large Bishop's ring, or haze; observations of heat received from the sun, as made with actinometers or pyrheliometers; observations of the polarisation of the blue sky light and of scintillation of the stars. It is proposed to incorporate the results of the inquiry in a general article on the subject of atmospheric transparency.

We have received notice from Dr. H. Hergesell, president of the International Committee for Scientific Balloon Ascents, that a new edition of the useful cloud atlas, prepared at the request of the International Meteorological Committee by MM. L. Teisserenc de Bort, H. Hildebrandsson and A. Riggenbach, and issued in Paris, under the special superintendence of the first named gentleman in 1896, will be undertaken if sufficient interest is taken in the matter by scientific men. We believe the atlas in question to be the best of the kind, and that the beautiful representations of various types of clouds have been of great use in connection with the scientific balloon and kite observations to which we have frequently directed attention. Dr. Hergesell (Strassburg) states that he will be glad to receive and to send to M. Teisserenc de Bort any suggestions from persons who have used the atlas, with the view of improving the proposed new edition.

The report and results of observations for the year 1903, issued by Mr. J. Baxendell, meteorologist to the Southport Corporation, shows that the high-class work carried on at the Fernley Observatory has been fully maintained. The various experiments on anemometers have been continued, and several improvements in connection with self-registering apparatus have been effected. A new instrument for continuously recording the variations in the inclination of the wind was designed and constructed by Mr. Halliwell, chief assistant at the observatory, and is now at work at the anemograph station. A useful article on the meteorology of Southport was prepared during the year for the "British Association Handbook" of local information for the Southport meeting. The usual interesting comparison of statistics of various health resorts is appended to the report.

At Leeds on May 12 Prof. Clifford Allbutt, F.R.S., opened a new public dispensary, the building of which has cost 33,000*l.* In the course of an address Prof. Allbutt remarked that medical men are engaged in destroying their own means of livelihood by preventing disease, and have attained very remarkable success. Diseases which were once rampant are now diminishing. Typhus has never been seen by some members of the medical profession. Typhoid fever has been reduced to a nominal amount, and there has been a reduction of pulmonary consumption all over England. Discoveries as to the nature of malaria have changed the face of important countries. Prof. Allbutt urged that preventing disease is more congenial than curing it, and suggested that a rise of the standard of general health would be achieved by the careful study of the origin and causes of disease in such an institution as that of the Leeds General Infirmary.

A copy of the *Peterborough Advertiser* of May 7 has been sent to us, containing the announcement that radium has been found in beds of Oxford Clay near Fletton, Huntingdonshire. No particulars are given, but a long descriptive article on the discovery suggests that it will make "brickfields better than gold mines." These sanguine anticipations will perhaps be tempered by the following extract from a paper by Prof. J. J. Thomson, read before the Cambridge Philosophical Society on February 15:—"Radium was found in garden soil from the laboratory garden, in the Cambridge gault, in gravel from a pit at Chesterton, in still greater quantities in sand from the sea-shore at Whitby, in the blue lias at Whitby, in powdered glass, in one specimen of flour, and in a specimen of precipitated silica."

A note in Nature of May 5 (p. 12) refers to some results obtained by Prof. A. Stefanini and Dr. L. Magri concerning the action of radium on the electric spark. Mr. R. S. Willows writes from the Cass Institute, Jewry Street, E.C., to say that he has been making observations on this subject for some time, and has come to practically the same conclusions as those arrived at by the Italian physicists. He remarks:—"My experiments are not sufficiently advanced to justify me in stating completely my results, but since the action can be greatly hindered by a magnetic field, I have come to the conclusion that it arises from the β rays given off by the radium."

In continuation of notes in previous numbers recording the progress of geographical research in Madagascar, the April issue of *La Géographie* contains an account of the geodetic and cartographical work carried out during 1902 and 1903. A sketch map showing the different triangulations and a table of determined positions accompany the article.

The May number of the *Geographical Journal* contains short articles of varied interest ranging over many parts of the subject. The president summarises the second season's work of the *Discovery* in the Antarctic regions. Captain Philip Maud writes on the exploration of the southern borderland of Abyssinia; Lieutenant Irizar on the rescue of the Swedish Antarctic Expedition; Colonel G. E. Church on the Acre territory and the caoutchouc region of south-western Amazonia; and Mr. Claud Russell on a journey from Peking to Tsitsihar. Dr. Vaughan Cornish contributes an elaborate discussion of observations on the dimensions of deep-sea waves, and there are papers on a bathymetrical survey of the lakes of New Zealand by Mr. Keith Lucas, and on peat moors of the Pennines by Mr. C. E. Moss.

The Geological Society of Belgium has issued a special memoir on the flow of underground waters in limestone regions. This is edited by M. E. Van den Broeck (Brussels, April). Having regard to the importance of determining the source of water used for drinking purposes, the underground course pursued by it, until it issues again in the form of springs, must if possible be ascertained. Observations on this subject are now brought forward and discussed. The use of colouring matters is generally regarded as the best means of determining the question, and especially with regard to the time occupied by the water in its transit through the strata. Fluorescein, which gives a green tint, has been held by a number of hydrologists to afford the most satisfactory results, while others have expressed the opinion that it serves to retard the flow of water, and that different matters in solution or in suspension have travelled more rapidly. It is, however, maintained that neither floating objects nor matters in suspension can give so true a notion of the flow as substances in solution, but the substance in solution must not augment the density. It is admitted that light, carbonic acid and peaty soil tend to decolorise the fluorescein. The influence of light is most important, and must be obviated. The decolorisation produced by carbonic acid can be counteracted by ammonia. It is generally concluded that fluorescein will prove the existence of communication between two points, and will give the best approximate idea of the time taken in transit. The fluorescope is necessary to detect its presence.

A photographic portrait of Francis Galton, admirable both in execution and as a likeness, is given in *Biometrika* (vol. ii. part iv.). The accompanying sketch of the same subject is also good and characteristic. The most important memoir in the part is Prof. Karl Pearson and Dr. Alice Lee's paper on the inheritance of physical characters. This embodies the fruit of many years' arduous labour, and establishes several results of high importance. Among these are the existence of statistical evidence of sexual selection, and the near approach to uniformity of the regression value of both physical and psychical characters as shown in fraternal inheritance. The former point receives indirect confirmation from a paper on assortative mating. Variation in *Ophiocoma nigra* is dealt with by Mr. D. C. McIntosh, and Mr. W. P. Ellerton contributes tables of powers and sums of powers of natural numbers up to 100. In the miscellanea, Prof. Pearson takes occasion to offer a vigorous defence of the position that "biometry is essentially a science of exact quantitative definition, and if it is to be of service in rendering anthropology an exact branch of science, it must replace vague ideas by numerically definite conceptions."

The results of the important experiments on the crossing of Japanese waltzing and albino mice, reports of which have already appeared, are collected and fully discussed by Mr. Darbishire in *Biometrika*, vol. iii. part i. While certain of the crossings gave results in accordance with Mendel's law, Darbishire shows reason for the view that ancestral influence cannot be excluded, and that Mendel's theory of the purity of gametes receives no support from the present series of experiments. Referring to the variability of "heterozygotes" and their divergence in character from the parental standard, the author observes:—"It seems to me that we have not got any further in this direction than Darwin had when he called phenomena of this kind reversions to ancestral condition." Incidentally, he shows that the results of his crossings afford no instance of telegony. Among the other memoirs in this part is the record of a striking and valuable experiment by Mr. A. P. di Cesnola on the protection from enemies secured by the coloration of *Mantis religiosa*. So far as the experiment went, the proof of protection enjoyed by the mantis in appropriate surroundings appeared to be complete, while it was also made clear that both green and brown forms are eaten by birds or ants when recognised. New ground is broken by Mr. Greenwood in a paper on the variability and correlation of the human viscera, and Prof. Weldon shows that Mendelian segregation does not, as has been suggested, obtain among human albinos in Sicily.

In the *Independent Review* for May, Dr. A. R. Wallace completes his survey of the chain of evidence connecting the "Islands of Wák-Wák" of the "Arabian Nights" with the Aru Islands, the home of the great bird-of-paradise. Hasan's journey through the "land of wild horses" is shown to refer to Tibet, whence the traveller crossed China to the sea, and eventually reached the Malay Peninsula. The apparently supernatural marvels encountered on the voyage from Malacca to the Aru Islands are all ingeniously demonstrated by Mr. Wallace to rest on a substratum of actual fact. Not that Hasan himself ever reached those islands, of which he was told by those who had accomplished the journey. Two separate legends appear to have been combined in the story of Hasan as we now know it. "The one is founded upon the magnificent plumage of the bird. . . . On the other hand, the cry 'wák-wák,' as distinctly stated by the General, gave the name to a mountain, and also to the islands themselves, and was said to be made, not by any bird, but by human heads which grew upon trees, and at daybreak gave forth this cry. . . . There is not a word in the whole story to show that there was thought to be any connection between the mysterious voices and the magical plumes."

We have received from the publishers (Messrs. Cassell and Co., Ltd.) a copy of a new popular edition of that useful little work, "The Field Naturalist's Handbook," originally compiled by the late Rev. J. G. Wood, and revised by the Rev. T. Wood. As the new edition is published at the price of one shilling, it is within the reach of all, and everyone interested in field natural history should buy a copy. Perhaps it may be well to remind our readers that the work is restricted to three groups specially favoured by collectors, namely, butterflies and moths, wild plants, and birds' eggs, and the proper seasons to look for the various kinds of each group are fully recorded in the tables. The scientific nomenclature, so far at least as Lepidoptera and birds are concerned, is of an old-fashioned type, but perhaps in the main it is none the worse for this, although some restriction of the scope of generic names would certainly have been advisable in the case of the ducks. In works of this nature it would perhaps be nowadays advisable to speak of "a scientific name" rather than "the scientific name" of a species. This little volume, which is an excellent example of careful editing, deserves a wide circulation.

A third edition, which has been revised and enlarged, of Mr. W. Perren Maycock's "First Book of Electricity and Magnetism" has been published by Messrs. Whittaker and Co.

"The Psychological Index, No. 10," a bibliography of the literature of psychology and cognate subjects for 1903, has been published in connection with the *Psychological Review*. The index has been compiled by Prof. Howard C. Warren, of Princeton University, with the cooperation of M. G. Revault D'Allonnes, of Paris; Mr. F. G. Bruner,

of Columbia University; and Mr. C. S. Myers, of the University of Cambridge.

Messrs. Pastorelli and Rapkin, Ltd., have submitted to us for inspection specimens of their patent "dial" barograph and of their student's standard barometer. In the case of the barograph we notice that the action of both dial hand and recording arm is simultaneous, the same movement controlling the two. Should the pen not indicate upon the chart a reading coinciding with that shown by the dial hand, this can be rectified by means of a milled head at the side of the dial case. Another milled head moves pen and dial hand simultaneously, and thus makes it possible to set the instrument to agree with a standard barometer, or to adjust for altitude correction. The student's standard barometer is constructed on the Fortin principle, and provides an accurate instrument at a moderate cost.

The new issue—that for 1904—of the "Statesman's Year-Book" (Macmillan, 10s. 6d. net), edited by Dr. Scott Keltie with the assistance of Mr. I. P. A. Renwick, contains several novel and valuable features. The introductory section of the volume includes statistical tables and diagrams exhibiting with admirable clearness the conditions of British trade and shipping from 1860 down to last year. A diagram is also included showing the distribution among the various fleets of the Belleville and other boilers. Panama, as an independent State, is accorded a separate section, as are also the See and Church of Rome, which in former issues have appeared together as a section under Italy. The statistics in other parts of the volume (which runs to 1398 pages) have been brought up to date by the aid of official returns. The annual publication of this compendium of the most trustworthy information available as to the various States of the world is a convenience to everyone interested in political geography and a necessity to all who have to make use of books of reference.

The additions to the Zoological Society's Gardens during the past week include a Black-eared Marmoset (*Hapale penicillata*) from South-east Brazil, presented by the Hon. Mrs. Algernon Bourke; four Smith's Dwarf Lemurs (*Microcebus smithi*) from Madagascar, a Bosman's Potto (*Perodicticus potto*) from West Africa, presented by Mr. Percy H. Stormont; a Mona Monkey (*Cercopithecus mona*) from West Africa, presented by Mr. W. Hughes; a Common Raccoon (*Procyon lotor*) from North America, presented by Mr. P. Estcourt Holland; three Blood-breasted Pigeons (*Phlogaenas luzonica*) from the Philippine Islands, presented by Dr. L. Wynne Davies; a Vervet Monkey (*Cercopithecus lalandii*) from South Africa, presented by Mr. J. Smyth; two Lobed Chameleons (*Chamaeleon parvilobus*) from South Africa, presented by Mrs. Cox; a Tarantula Spider (*Avicularia avicularia*) from the Lower Amazons, presented by Mr. J. W. A. Watkins; an Antilopine Kangaroo (*Macropus antilopinus*) from North Australia, a Yellow-handed Howler (*Mycetes beelzebul*) from the Lower Amazons, a Senegal Galago (*Galago senegalensis*) from Senegal, a Common Wolf (*Canis lupus*), two European Sousliks (*Spermophilus citellus*), European; a Dingo (*Canis dingo*) from Australia, two Grooved Tortoises (*Testudo calcarata*) from South Africa, deposited; two Spoonbills (*Platalea leucorodia*), two Cayman Island Amazons (*Chrysotis caymanensis*) from the Grand Cayman, purchased; a Corean Bull (*Bos taurus*, var.), three Crab-eating Raccoons (*Procyon lotor*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

June Meteors.—June does not usually prove itself a very prolific month in furnishing meteors, and a sufficient reason is found in the strong twilight prevailing in high northern latitudes at this period. But there are a few very interesting showers to be observed. Very brilliant meteors are often directed from near Antares (α Scorpii), the radiant being at 252°–21°. Nearly every year one or several fireballs from this southern stream appear over England, but the observations are often not sufficiently exact and numerous for their real paths to be determined.

There is an active radiant in June from 313°+60° near α Cephei. These meteors are swift, and they may quite possibly be connected with comet 1850 I., which has a radiant on June 23–24 in same position.

There is another shower in Cepheus from 335°+57° near ζ, which is particularly well defined at midsummer, and seems to be actively continued during July, August and September.

June is also a good month for Cygnids. There are fairly active showers from β, θ, δ and α Cygni. In June, 1887, a number of meteors were seen diverging from radiants at 252°+11° (near α Herculis), 274°+69° (ω Draconis), and 280°+43° (α Lyræ). It is probable that all these showers recur annually, though with variable strength.

A Spectroheliograph for the Catania Observatory.—Prof. Orlando, the Italian Minister of Public Instruction, has granted L3000 (125*l.*) to the Observatory of Catania for the purchase of a spectroheliograph. The acquisition of such an instrument will enable Profs. Ricco and Tacchini to participate more fully in the proposed international daily study of the solar phenomena, and thereby add to the important solar work which has already been performed at the Observatory of Catania.

The Parallax of λ Andromedæ.—In a letter to the May issue of the *Observatory*, Mr. J. E. Gore directs the attention of those astronomers who are engaged in parallax determinations to the spectroscopic binary λ Andromedæ. From a consideration of the published elements it appears that the mass of the bright component of this system is only about one-tenth that of the sun. In order that a body with this mass and with a surface luminosity equal to that of the sun might appear as bright as λ Andromedæ (mag. = 4·0), it would have to be comparatively near to the earth. Mr. Gore's theoretical value of the parallax is 0″·34, and this is probably too low, for a comparison of their respective spectra leads to the conclusion that the surface luminosity of the sun is the greater. The star has a considerable proper motion, equal to 0·0157 in R.A. and 0″·425 in declination, according to the Greenwich ten year catalogue.

The Repsold Registering Micrometer.—In No. 3943 of the *Astronomische Nachrichten*, Prof. K. Oertel discusses the results obtained with the Repsold self-registering micrometer which is attached to the meridian circle of the Munchen Observatory.

An analysis of these results leads Prof. Oertel to claim many advantages for this instrument as compared with the older form of micrometer. Among other advantages he mentions the following:—The personal equation is either entirely absent or extremely small. Differences of magnitude in the observed stars do not influence the results. The accuracy of the results is greater than in the older method. The observations take less time, one observer being able to observe between thirty and forty stars, in both co-ordinates, during one hour.

The Spectroscopic Binary β Aurigæ.—In an article published in No. 3944 of the *Astronomische Nachrichten*, Prof. Vogel contests the validity of Herr Tikhoff's conclusions (*Astronomische Nachrichten*, No. 3916) concerning the system of the spectroscopic binary β Aurigæ, which stated that the system was probably made up of two separate pairs, and that the period was 3d. 23h. 30·4m. From the reduction of thirty-nine spectrograms obtained between December 22, 1903, and February 9, 1904, Prof. Vogel concludes that the period is 3d. 23h. 2m. 16s. ± 5s., and that the orbit is nearly circular in form. He also states that the reason for believing the system to be made up of *four* bodies is, to him, obscure.

THE EDUCATION OF EXAMINERS.[1]

THE subject that I have chosen for my presidential address may at first sight seem far from inviting. Yet, in spite of the unusual title of my paper, I undertake to say that most of you present here to-day will follow the results which I shall lay before you with ease, and will find a growing interest in certain ideas which cannot but prove novel to those of you who have not before thought of examiners as belonging to the human race, and therefore capable of education.

In a sense we are all examiners. We note and tabulate events and their causes. We distribute mankind into ethnological groups, or compare them as industrial workers. We ascertain their wants and their means of satisfying those wants. We examine and record the growth of custom, the physical and mental development of the human being, the changes in the mind itself and the order of such changes, the progress and decay of language, the distribution of wealth, the progress of society. Even the laws of statistics are submitted to examination.

Thus, side by side with the advance of theory in connection with all the sciences that fall under this section (archæology, education, mental science, philology, political economy, sociology, statistics), goes the scrutiny of results. It is justifiable, therefore, to think that an examination of methods of examination, even in connection with only one of those subjects, will throw a light upon such methods in general. I propose to-day to consider that small part of education which consists in the testing of the results of study by written papers.

You will perhaps wonder how it is that I have taken such an interest in the doings of examiners. The fact is that I am one of the few persons who have been for a lengthy period in the position of an examiner of examiners. In the position which I held in the Civil Service Commission for nearly fifteen years, it was my daily task to consider the character of the papers set by some of the highest dignitaries at Oxford and Cambridge, and other universities, to candidates for appointments in the English Civil Service. I had, moreover, to investigate the marking of the written answers of candidates, and to say whether the general results appeared to me to be fair and trustworthy.

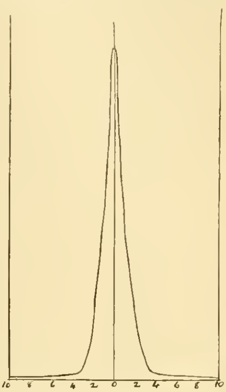
Of course, it will be understood that there are good as well as bad examiners. If the methods of good examiners are compared together, it will be found that they tend to uniformity, and that their results have certain characteristics in common. Whereas the methods and results of bad examiners differ from one another in every conceivable way.

But how are these results to be shown? It is not possible to obtain such information by running the eye down the totals awarded to candidates in the mark-sheets. Patient study will no doubt do something, but, where figures occur irregularly, it is hard to appreciate their import without definite classification.

In these days of the almost universal use of "squared" paper, all that is required is to find the percentages of candidates obtaining marks between the limits named, and to mark them off by counting the squares, say five candidates to a square. If the maximum in the subject is not 100, then it is only necessary to reduce the marks to that scale. By joining the top points of the vertical lines, which we call ordinates, the characteristic curve of the examiner is obtained, or, what is even more satisfactory, if black columns are raised on the bases 0 to 10, 11 to 20, &c., to show the number of candidates within these limits of marks, the result is a number of stepping-stones, shown in silhouette, and rising and falling in general harmony with the curve.

Difficulties presented themselves to me as soon as I began to plot the results of examiners from their mark-sheets. Until this had been done it was impossible to analyse the character of the marking, even after hours of study of the mark-sheets themselves. But as soon as the graphical representation had been arrived at, the whole matter was simplified. It was only necessary to determine whether there was any special form of curve to which the many varieties that have been placed before you ought to tend, or whether each subject, and even each examiner, might be properly represented by a different curve. I very soon became convinced that there was a tendency among the best examiners in many subjects to obtain results which gave the graphical form of a gendarme's hat (Fig. 2).

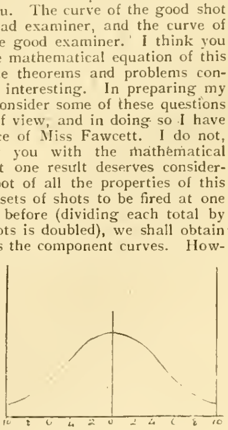
This form is one which is recognised by mathematicians as belonging to the so-called curve of "errors." I can best illustrate what is meant by this curve by supposing that some person in this room, experienced in the use of fire-arms, were asked to fire shots at a paper target on which a vertical straight line had been drawn as the mark to be aimed at. After a large number of shots had been fired, you would find that the holes in the target were arranged in about equal numbers on either side of the line, and that very few had actually hit the mark. If the distance of each shot from the centre line were measured and entered on a table, we should find so many falling within one inch of the line, so many between one inch and two inches, and so on. The curve now placed before you (Fig. 1) is produced by showing the number of shots falling within one inch on one side as a column of proportionate height erected on a base reaching one inch from the centre line. Similarly the column showing the number between one and two inches is drawn on a base between one and two inches from the centre line, and so on.



Deviation in inches.

FIG. 1.—Curve showing Pistol Practice at Vertical Line (good shot).

Now I show you a second curve (Fig. 2), in which the pistol has been put into the hands of an inexperienced person. You will at once perceive that these two curves are familiar to you. The curve of the good shot resembles the curve of the bad examiner, and the curve of the bad shot the curve of the good examiner. I think you will spare me giving you the mathematical equation of this curve, although many of the theorems and problems connected with it are extremely interesting. In preparing my paper to-day I have had to consider some of these questions from a mathematical point of view, and in doing so I have had the inestimable assistance of Miss Fawcett. I do not, however, propose to weary you with the mathematical treatment of the subject, but one result deserves consideration, because it is at the root of all the properties of this curve. If we allow the two sets of shots to be fired at one target, and classify them as before (dividing each total by two, since the number of shots is doubled), we shall obtain a curve of the same family as the component curves. However many times the process is repeated, each marksman will repeat his identical curve—on the supposition that he does not improve owing to practice—and of course the resultant curve due to both sets will be repeated.



Deviation in inches.

FIG. 2.—Curve showing Pistol Practice at Vertical Line (inexperienced shot).

Instead of taking only two performers with the pistol of unequal merit, we may bring within our view a considerable number in an ascending or descending scale of accuracy, and trace upon one sheet a series of these curves. Here is such a series (Fig. 3).

In each of these curves it should be noticed that the extreme portions never touch the base line, but they approach closer and closer to that line, so that the area enclosed in each case between it and the curve in question

[1] Abridged from an address delivered before Section D of the South African Association for the Advancement of Science on April 5 by Mr. E. B. Sargant, Education Adviser to Lord Milner.

depends upon a portion on each side of the middle ordinate which is at a measurable distance from that ordinate. Where the practice is accurate, the portion of the whole figure that may be safely excluded in calculating the area is much larger than in the cases where the shooting is wild.

A measure of the accuracy of the marksmen is obtained by drawing an ordinate to divide into equal parts the half area to the right or left of the middle ordinate, and estimating the distance between these two ordinates.

The whole area under consideration represents the total number of shots, and is therefore the same in the case of each curve. For the sake of simplicity we may suppose that 100 shots are fired. It is not true that that number of shots will in any case give the exact curve. We should only obtain its precise form by firing an infinite number of shots and then reducing the whole to a percentage. But for the sake of simplicity in our argument we will talk of 100 shots as the number that has been fired, and say that the area is proportional to that number. We see, then, that all the areas enclosed by each of these curves respectively and the base line are equal; and this gives us a simple way of plotting any one series if a single curve has been drawn. It is only necessary to suppose the curve to be stretched to a certain extent in either the horizontal or vertical direction, and to be contracted to a proportionate extent in the other direction, in order to pass to another curve of the series. In fact, if one of the curves were painted on a stretched india-rubber sheet, all the other curves could be got from it by pulling the sheet in one direction and slacking it off in the other.

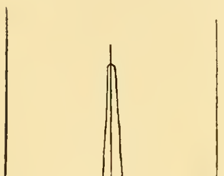


FIG. 3.—Series of Curves of "Error."

Another plan would be to bend a loop of wire into the form of one of the curves, and to place a lamp behind it so as to throw the shadow upon a screen. The loop and lamp might then be easily made to move in such a manner that the shadows in the successive positions gave the whole series of curves.

You will notice in the figure the points which show the intersection of neighbouring curves with one another. This is called, in mathematical language, the envelope of the family of curves. In this case it is a portion of two rectangular hyperbolæ.

Now, instead of our performers with the pistol, let us take the case of a series of examiners. As soon as I had observed that the curves of good examiners tended to approximate to the curve of errors, I cast about for the reason of this similarity. It is not far to seek. If we consider one particular candidate as the mean candidate, that is, a candidate such that there are as many above him as below him, we shall see how natural it is that the candidates should group themselves about this central figure as the pistol shots about the mean shot. It is clear that the curve of the good examiner should resemble the curve of the bad shot. The object of examination is to separate the candidates from one another as widely as is permissible under the given conditions, while the object of the target-practice is to get as many shots near the central line as possible.

Here we come to a most important limitation. You have already noticed that the curves we have been considering never touch the base line, that is to say, given a sufficient number of candidates, there will always be one or two removed to an extraordinary degree from the bulk of their fellows. But the examiner is obliged to give marks within certain limits, which he fixes arbitrarily as 0 and 100. If he were to place his zero point at a very great distance from the middle point, representing 50 marks, he would be able, no doubt, to make allowance for extraordinary candidates; on the other hand, the bulk of the candidates would be placed so close together that he would not be able to distinguish between them in any satisfactory manner. He is therefore bound to choose points such that the areas enclosed between the base line and the curve which lies beyond those points are very small compared with the areas up to the middle line. All the candidates beyond those points must be considered as having either nought or full marks.

Now you will see, I think, how an examiner in English composition, especially if he is a university man who has become acquainted with the finest examples of literature, tends to get a very steep form of curve (Fig. 4). He looks at some one paper, which differs to a considerable extent as regards both style and matter from the mean paper, and says, "This paper should have 80 marks at least." But then he thinks, perhaps unconsciously, "How do I know that, before finishing the pile of papers before me, I shall not find a budding Milton or Addison or Charles Lamb? If I give this candidate 80 marks, shall I be able to assign its true value to a composition of such extraordinary merit?" So he only awards 60 marks to the composition, and finds almost certainly, when he comes to the end of his pile, that no candidate has received any mark near 100. It is too late now to begin marking the papers all over again, and accordingly he sends in returns which do not serve to distinguish between the candidates in English composition to the same extent as they are distinguished in geometrical drawing, for example. The result is that a good candidate in the former subject is treated unfairly as compared with a good candidate in the latter subject.

FIG. 4.—English Composition.

Again, we see why a curve (Fig. 5) based on marking dictation papers by the system of deductions is so abnormal. In this case, the examiner, without considering minor defects, makes a certain deduction for each mistake in spelling. If 10 marks are taken off for each mistake, all candidates having more than ten errors receive no marks, whereas if we were to assign negative marks, the curve of errors would almost certainly be reproduced, the mean ordinate being below the zero point. The divergence which you perceive near the point representing full marks is due to there being a good many candidates who make no important mistakes. If minor defects, such as refinements of punctuation, were considered, and the scale stretched beyond 100, this divergence would also disappear.

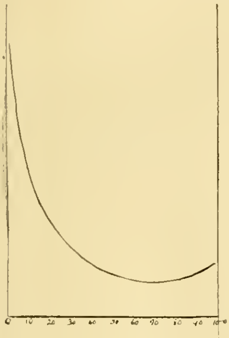
The problem which presented itself was how to bring these very different results into some accord. In order to give equal weight to various subjects having the same maximum, it seemed to me necessary that the examiners should have a common standard to work up to. Accordingly, during the latter period of my service with the Civil Service Commission, I caused such a diagram as has been placed before you to be printed on the sheet containing the examiner's report of his work. On that diagram, also, was printed a curve resembling a moderate sized gendarme's hat. If, as often happened, the examiner had 1000 papers to mark, he was requested to go through a batch of 100 taken at hazard, and to plot his curve upon the diagram. After a few examinations an old hand would probably find that his curve for the first 100 resembled closely the standard curve before him, but a fresh examiner might find himself altogether beside the mark. In such a case he was asked

to put aside the first 100 papers and to begin marking the fresh papers on such different lines as would, in his judgment, produce an approximation to the normal curve. On the supposition that he had achieved that result for the second 100, and continued to find that his curve was pretty constant for the third 100, fourth 100, and so on, he was asked at the end of all the papers to re-mark the first 100.

You might imagine that many examiners disliked having to place themselves upon this bed of Procrustes, but in the generality of cases it was not so. They positively took a delight in examining themselves. The process became one of self-education in marking.

Before leaving this part of my subject I should like to warn you that certain causes, which an examiner cannot always control, may make it difficult to obtain such an ideal curve as I have shown. It is not possible for me to enter fully into this part of the subject, but I will point out one cause at least that he can control—I mean the examination paper.

Good marking will not compensate for a bad paper. Every candidate must have his chance, in some question or other. Otherwise the examination is like a hurdle-race in which the hurdles are so high that a considerable number of candidates find themselves stopped from reaching the goal at all. The curve, in such a case, tends to assume a shape of this kind, mounting very rapidly to the zero line (Fig. 5)—just the curve, in fact, which we have already seen in connection with a dictation paper. In this case it is not the marking which is wrong, but the examination paper.



Number of marks gained.

FIG. 5.—Dictation Paper.

Accordingly, I found in practice that it was necessary to point out to examiners, before ever their papers were proposed in manuscript, that they ought to divide their questions roughly into (say) three portions, of which one portion could be answered by candidates of inferior power, a second should be within the range of mediocre candidates, and a third only possible to candidates who might be classed as good to excellent. The result of these directions was that examiners soon found little difficulty in spreading out their candidates in the desired way. In setting their questions they had before their eyes the little gendarme's hat.

Among the causes, beyond the control of the examiner, which may interfere with the formation of this curve, we must reckon as in the first rank:—(1) such a small number of candidates as does not give fair play to the law of probabilities; (2) any selection of candidates by a preliminary examination or other means.

With regard to the causes just named, I will only say that it has been found that the method can be applied successfully when there are not less than one hundred candidates, and that, even below this number, the curve, though irregular in formation, gives us very useful information as to an examiner's capacities. With regard to the second cause, a great deal can be done to produce a satisfactory curve by setting such questions in the further papers as are only addressed to the candidates who remain after the preliminary sifting.

I trust that I have now fulfilled the promise with which I started, namely, to show you how examiners themselves may be examined; and not only this, but you will understand that it is possible to educate examiners so as to enable them to form a much more accurate and sustained judgment of a large number of candidates than would have been within their power without such preliminary guidance.

THE CHEMICAL REGULATION OF THE SECRETORY PROCESS.[1]

THE researches which we wish to bring briefly before the Royal Society deal with the mechanism of adaptation to changes in the food and the chemical correlation of the activities of different organs engaged in the digestion and assimilation of the food.

According to Pawlow, the secretion of the pancreatic juice is exactly comparable to the secretion of saliva, and is effected by a nervous reflex. The starting point of this reflex is the stimulation of the duodenal mucous membrane by the chyme, or by substances such as oil, ether, or oil of mustard. Not only is the pancreatic juice turned out into the intestine just at the time when it is required, but, according to Pawlow, the composition of the juice varies according to the food, the proteolytic ferment being increased by a diet of meat, while the amylolytic ferment is increased by a starchy diet. This adaptation of the glandular activity was ascribed by him to a species of "taste" in the mucous membrane. It was imagined that the different constituents of the food excited different nerve endings, which, in their turn, caused reflex activity of different mechanisms in the pancreas itself. The field of these assumed reflexes was considerably narrowed by the researches of Popielski (*Gazette Clinique de Botkin*, 1900) and Wertheimer (*Journal de Physiologie*, vol. iii. p. 335, 1901), who showed that the introduction of acid into the duodenum was productive of secretion even after destruction of all nerve connections of the pancreas and alimentary canal with the central nervous system, and even after extirpation of the sympathetic ganglia of the solar plexus. It was with a view to determine the mechanisms of this reflex secretion of the pancreas, as well as of the adaptation of the pancreatic secretion to variations in the food of the animal, that we began our researches.

The last named authors had also shown that the secretion occurred, but in smaller quantities, if the acid was inserted in any part of the small intestine, with the exception of the lower end of the ileum. It was thus easy to examine the effects of the introduction of acid into a loop of ileum in which all nerve connections with the pancreas, or with the rest of the body, had been destroyed. This crucial experiment had, curiously, not been performed by previous workers in the subject. On carrying it out, we found that destruction of all nerve connections made no difference to the result of introducing the acid. The pancreatic secretion occurred as in a normal animal. It was therefore evident that we had to do here with a chemical rather than a nervous mechanism. Previous work had narrowed the question down to such a degree that the further steps were obvious. We knew already that the introduction of acid into the blood-stream had no influence on the pancreas; hence the acid introduced into the intestine must be changed in its passage to the blood-vessels through the epithelial cells, or must produce in these cells some substance which, on access to the blood stream, evoked in the pancreas a secretion. This was found to be the case. On rubbing up the mucous membrane with acid, and injecting the mixture into the blood-stream, a copious secretion of pancreatic juice was produced. It was then found that the active substance, which we call *secretin*, was produced by the action of acid from a precursor in the mucous membrane, probably in the epithelial cells themselves. Once formed by the action of acid, it could be boiled, neutralised, or made alkaline, without undergoing destruction. The precursor of the substance (*pro-secretin*) cannot be extracted by any means that we have tried from the mucous membrane. Even after coagulation of the mucous membrane by heat or alcohol, however, secretin can still be extracted from the coagulated mass by the action of warm dilute acid.

We have not yet succeeded in determining the chemical nature of secretin, though we have obtained chemical evidence which will serve to exclude certain classes of substances. Thus the fact that it will stand boiling shows that it is neither a coagulable proteid nor a ferment. It is soluble in 90 per cent. alcohol in the presence of ether, but it is insoluble in absolute alcohol and ether. It is slightly diffusible through animal membranes. It can be

[1] Abstract of the Croonian Lecture. By Dr. W. M. Bayliss, F.R.S., and Prof. E. H. Starling, F.R.S. Read before the Royal Society, March 24.

filtered through a gelatinised Chamberland filter. It is not precipitated by tannic acid, thus excluding bodies of alkaloid nature as well as diamido-compounds. This evidence, slight though it is, points to secretin being a body of relatively small molecular weight and not a colloid. It may be compared to the active principle of the suprarenal glands, adrenalin, which has been obtained in a crystalline form and the chemical constitution of which has been approximately determined. This is, indeed, what one would expect of a substance which has to be turned out into the blood at repeated intervals in order to produce in some distant organ or organs a physiological response proportional to the dose. The bodies of higher molecular weight, such as the toxins, which owe their activity, according to Ehrlich, to the fact that they can be directly assimilated by the cells of the body, and built up into the protoplasmic molecule, always give rise to the production of anti-bodies, a process which, while not preventing necessarily their utilisation in the body, would prevent their acting as a physiological stimulus to certain definite cells. Adrenalin and secretin on the other hand belong to the class of drugs which act by their physicochemical properties, and the physiological effect of which is determined by the total configuration of their molecule. It was suggested to us early in our experiments that the secretion of pancreatic juice, evoked by secretin, was essentially a sudden production of an anti-body; such a sudden production is unknown in the animal body, and the anti-character of the secretion is at once negatived by the fact that secretin can be mixed with a freshly secreted juice without in any way destroying its efficiency.

Like adrenalin, secretin is extremely easily oxidised, and it is probable that it is got rid of in this way from the body, since, even after repeated injections of secretin, it is impossible to find this substance or any precursor of it either in the pancreas, the urine, or other tissues of the body. Just as in the case of adrenalin, so we find that secretin is not specific for the individual or species. An extract of the mucous membrane of the dog will evoke secretion in the pancreas of the frog, the bird, rabbit, cat, or monkey. In the same way the pancreatic secretion of the dog can be excited by injection of secretin prepared from the intestine of man, cat, monkey, rabbit, fowl, salmon, skate, frog, or tortoise. The evolution of this mechanism is, therefore, to be sought at some time anterior to the development of vertebrates.

The action of secretin is not confined to the pancreas. It has long been known that the pancreatic juice, in order to exert its full activity on the food stuffs, needs the simultaneous presence of bile, and the fact that in many cases the two fluids are poured into the duodenum by a common orifice shows the close connection which must exist between them. Digestion of fats is impossible unless both fluids have access to the gut, and even in the digestion of carbohydrates, as was shown by S. Martin and Dawson Williams many years ago, the presence of bile greatly hastens the digestive powers of the pancreatic juice. Whenever, therefore, a secretion of pancreatic juice is required, a simultaneous secretion of bile is also necessary. It is interesting to note that this simultaneous secretion is provided for by the same mechanism by which the secretion of pancreatic juice is evoked. If the flow of bile be determined by measuring the outflow from a cannula placed in the bile duct, it will be found that introduction of acid into the duodenum causes a quickened secretion of this fluid. The same increase in the secretion of bile can be produced by injecting solutions of secretin into the blood stream. This influence of secretin on the liver has been fully confirmed by Falloise. This observer has shown that acid extracts of the intestinal mucous membrane cause an increase in the bile secretion most marked when the extract is made from the duodenum and diminishing as the extract is taken from the lower parts of the gut, that from the lower section of the ileum being quite ineffective.

The discovery of secretin has placed in the hands of physiologists the power of controlling the activity of a gland by purely physiological means, and we have taken opportunity of the control thus acquired to investigate the exact character of the changes induced in the pancreas under this physiological stimulus. So far as we can tell secretin has no specific influence on any one constituent of the pancreatic juice. When injected it causes secretion of a juice which is normal in that it resembles the juice secreted on entry of food into duodenum, and contains a precursor of trypsin, amylopsin, and steapsin. Secretin, in fact, appears to cause the pancreatic cells to turn out the whole of the mesostates which they have accumulated during rest in preparation for the act of secretion. If secretin be injected at repeated intervals until the gland will no longer respond to the injection, it is found on microscopic examination that the cells have discharged the whole of their granules. In sections stained with toluidine blue and eosin the whole of the cells stain blue in marked contrast to the normal resting gland, where one-half or two-thirds of the inner margin of the cells is taken up with brilliantly stained red granules. This effect is not produced in all cases. In some animals we have injected secretin at frequent intervals over a period of eight hours, and obtained at the end of the experiment a secretion as vigorous as after the first injection. The pancreas in this case was evidently not fatigued, and on killing the animal and examining this organ microscopically it was found to give the typical picture of a resting pancreas. One may say, therefore, that under healthy conditions the activity of the pancreas is two-fold in character, and that the normal stimulus of secretin excites not only a breaking down of the protoplasm and a discharge of granules, but also a building up of the protoplasm and a new formation of granules. So marked, in fact, is this power of self-restitution that it is often advisable to diminish the resistance of the animal by bleeding or other means if it is desired to obtain a specimen of exhausted gland.

A study by Mr. Dale of the stages of exhaustion carried out in this way has brought to light a remarkable behaviour in the cells of the pancreas, to which we have no analogies in other secreting glands of the body. After the discharge of the granules the cells seem to undergo a still further involution, losing the whole of their chromophile substance, diminishing in size or undergoing vacuolation, and finally being transformed into cells undistinguishable from those which have long been known as forming the so-called "islets of Langerhans." Mr. Dale has, in fact, shown that in all probability these "islets," which are generally regarded as pre formed structures, really represent stages in the functional activity of the secreting cells of the gland, and he is of opinion that the activity of the gland is always associated with a cycle of changes in which the islets are formed, to be afterwards regenerated into secreting tissue. Other observers have noted in the embryo a development of secreting tubules from tissue undistinguishable from the "islets of Langerhans," and it is interesting to note that the depletion of the gland caused by long starvation has a similar effect to that caused by over-excitation, namely, the conversion of a large proportion of the gland tissue into "islet" tissue.

So far we have dealt only with the correlation of the activities of the cells lining the intestinal tube with those forming the masses of the pancreas and liver, and have seen that a very large part in this correlation is played by a chemical substance which acts, so to speak, as a chemical messenger between these various organs. A striking feature, however, of the pancreas is its alleged power of adapting its secretion to the nature of the food taken in by the animal. It has been stated by Pawlow that according as the food consists chiefly of proteids, carbohydrates, or fats, so do we find a relative preponderance of the ferments acting respectively on each of these three classes of foods. The evidence on which this statement is based, although lending to it considerable support, is not absolutely convincing. Vasilieff (*Archives des Sciences Biologiques*, St. Petersburg, 1893) examined the pancreatic juice of dogs which were fed on meat, or bread and milk alternately for periods extending over several weeks for each kind of diet. This observer found that the transition from bread and milk diet to a meat diet caused a rapid rise in the proteolytic power of the juice, which reached its maximum after several days of meat feeding. A return to a diet of bread and milk caused a slower fall in the proteolytic power of the juice, but a rise in the amylolytic power. Similar results were obtained by another pupil of Pawlow—Jablonsky (*ibid.*, 1896)—who also extended his observations to the fat-splitting ferment. At the time that these observations were made the function of enterokinase was unknown, and it is there-

fore impossible to say what proportion of the trypsinogen of the juice secreted in these experiments had been converted into trypsin by the small amount of intestinal mucous membrane at the mouth of the duct. While, therefore, we are unable to ascribe much importance to the results as regards the proteolytic power of the juice, there seems no reason to doubt the results obtained by these workers as regards the starch-digesting power of the juice. In 1899 Walther (*ibid.*, 1899, vol. vii. p. 1) made a series of observations on a dog with pancreatic fistula in order to determine whether the amounts of ferments secreted were determined by the nature of the food at any given meal. He was satisfied that his results showed that, even without prolonged adherence to one diet, the composition of pancreatic juice was adapted to the nature of the meal taken. His results do not entirely bear out his contentions, as is seen by the following table, in which it will be noticed that although milk contains no starch, it evokes the secretion of a large amount of amylopsin, and that meat causes a secretion of more steapsin than does milk, although this latter contains much more fat than the meat diet.

TABLE I.—*Results of Walther's Experiments.*

Diet	Total amount of enzyme secreted		
	Proteolytic	Amylolytic	Fat-splitting
600 c.c. milk ...	1044	2310	4125
250 grams bread ...	2360	6343	1218
100 grams meat ...	1720	2498	4410

Of course Walther, as well as the other observers mentioned, regard the adaptation as determined by the stimulation of special nerve endings in the mucous membrane by each constituent of the food, a conclusion hardly borne out by the results just quoted. Another disturbing factor in these experiments is the large variation in total quantity of juice secreted with different food-stuffs.

TABLE II.—*Amount of Pancreatic Juice Secreted for different Food-stuffs (Walther).*

Food	Hours of secretion									Total amount
	1	2	3	4	5	6	7	8	9	
600 c.c. milk	8·2	6·0	23·0	6·2	1·75	—	—	—	—	45 c.c.
250 grams bread ...	35·5	47·0	20·5	16·5	10·0	12·0	6·5	3·0	—	151 ,,
100 grams meat ...	45·0	52·0	35·0	9·75	—	—	—	—	—	142 ,,

The quantity of juice secreted will depend on the amount of secretin turned into the circulation, and this, in its turn, on the amount of acid entering the duodenum from the stomach. The amount of juice will, therefore, be measured by the stay and resistance to digestion of the substance in the stomach rather than to any direct nervous or other influence of the duodenal contents on the pancreas. A repetition of Walther's experiments by Popielski (*Centralblatt f. Physiologie*, vol. xvii., 1903), working independently, has in fact led the latter to deny altogether the adaptation of the pancreatic juice to the nature of the food. Popielski concludes from his experiments that variations in the juice depend only on the intensity and duration of the stimulus, the intensity of the stimulus determining the amount of enzymes, whilst its duration determines the total quantity of juice.

In the meantime the question had been attacked from another side. It had been shown by Fischer and Niebel (*Sitzungsberichte der K. Preuss. Akad. d. Wiss.*, 1895, p. 73), as well as by Portier (*C. R. Soc. de Biologie*, 1898, p. 387), that watery extracts of the pancreas of the cow, horse, and dog had no influence on lactose. Weinland in 1899 confirmed these results so far as concerns the pancreas of dogs on an ordinary diet free from milk. On the other hand, he found that extracts of the pancreas of dogs, which had been fed for several days on milk, sometimes with the addition of lactose, invariably contained lactase in considerable amount, and these results have been confirmed lately by Bainbridge working in our laboratory. Here then we have a definite instance of adaptation of the pancreas, the pancreatic juice or pancreatic extracts of dogs on normal diet containing no lactase, while the administration of lactose to these animals causes the appearance of lactase in both cases. Since in this case we have to determine, not simply an increase or diminution in the amounts of ferments always present in the juice, but the presence or absence of a definite substance, this was evidently the best starting point for an investigation of the mechanism by which the pancreas can adapt itself to the nature of the food, an investigation which has been carried out and completed by Dr. Bainbridge.

What are the limiting conditions? In the first place the reaction is absolutely specific. Unless the animal is taking lactose in its diet no lactase is ever found in the pancreas or in its secretion. The pancreas of new-born animals, for instance, is quite free from lactase, which, however, makes its appearance two or three days after birth as the result of the milk diet. The production of lactase is not a direct reaction of the pancreas to the presence of lactose in the blood, since subcutaneous or intravenous injection of lactose does not cause the appearance of lactase in the pancreas. The intestinal mucous membrane of all animals, whether on a milk diet or not, contains lactase and has an inverting action on lactose. It might be thought therefore that the production of lactase by the pancreas was a reaction to the presence of the products of inversion of lactose in the blood. This was found not to be the case. Subcutaneous injection of galactose for several days was not followed by any appearance of lactase in the pancreas or its juice. Nor was the appearance of lactase due to the increased production of this ferment in the mucous membrane, and its escape into the blood. Injection of an extract of mucous membrane rich in lactase, repeated several days in succession, was not followed by any appearance of lactase in the pancreas. Injection of lactose into the duodenum, and the subsequent injection of secretin after an interval of one hour, was inefficacious in causing the appearance of lactase in the pancreatic juice. For the production of lactase in the pancreas, or its juice, it is therefore necessary that lactose should act on the intestinal mucous membrane for some time. The reaction is a slow one, like the adaptation in Vasilieff's experiments, and is certainly not due to the stimulation of certain nerve endings in the mucous membrane by the lactose.

The problem was somewhat similar to that presented by the action of acid in the duodenum, since this introduced into the duodenum produces secretion of juice, whereas, when introduced into the blood stream, it has no effect whatever on the pancreas. The question suggested itself whether, under the influence of lactose, a special secretin was formed in the intestinal mucous membrane which, on access to general circulation, evoked the formation and secretion of lactase by the pancreas. Secretin was therefore made in the usual way (*i.e.* acidification, boiling, neutralisation, and filtering) from the mucous membrane of milk-fed dogs. The secretion evoked by the injection of this liquid resembled that obtained from the injection of ordinary secretin, and contained no lactase.

Yet it was evident from the results already obtained that lactose must act on the pancreas through the mucous membrane of the intestine. An extract was therefore made from the mucous membrane of the whole small intestine of a milk-fed dog. This was filtered through muslin, and about 10 c.c. injected subcutaneously into a biscuit-fed dog once a day for three days. The dog was then anæsthetised, a cannula placed in its pancreatic duct, and ordinary secretin injected. A flow of pancreatic juice was obtained, and this juice was found to contain lactase. This experiment was performed eight times, and in each case the juice obtained from a biscuit-fed dog which had been injected with an extract of the mucous membrane of a milk-fed dog contained lactase.

TABLE III.—*Effect on Milk Sugar of Pancreatic Juice from "Biscuit-fed" dogs, which had received Subcutaneous Injections during three days of Extracts of the Mucous Membrane of "Milk-fed" dogs.*

The figures represent c.c. of lactose solution which reduced 50 c.c. Pavy's solution.

Exp.	Controls: Solution of lactose	Controls: Lactose+pancreatic juice (boiled)	Lactose+pancreatic juice	Percentage of inversion
1 ...	7·4	...	6·8	18·1
2 ...	8·2	8·2	7·6	16·5
3 ...	8·2	8·15	7·85	9·7
4 ...	7·95	7·9	7·65	8·5
5 ...	7·8	..	7·5	8·8
6 ...	7·0	7·05	6·75	8·1
7 ...	4·1	...	3·75	20·8
8 ...	9·25	...	8·2	25·9

Here then at last we have some glimpse into the mechanism of the adaptation of the pancreas to the nature of the food. As the result of injection of lactose some substance which we may call x is produced in the mucous membrane of the small intestine. This substance is carried by the blood to the pancreas, and there slowly gives rise to the formation of lactase which is turned out in the juice when secretion is excited by the entry of acid chyme into the duodenum. We have no knowledge as yet as to the nature of this substance x. All we can say is that it is destroyed at a boiling temperature, since boiled extracts of the mucous membrane of milk-fed dogs do not, when subcutaneously injected, cause the appearance of any lactase in the pancreatic juice of biscuit-fed dogs.

Whether the qualitative adaptation of the juice in respect of its trypsin, amylopsin, and steapsin is carried out in a similar fashion we cannot as yet say. We hope that an investigation of the mechanism of this adaptation, which is now proceeding, may throw light, not only on the factors involved, but also on the nature of the substance which is formed in the mucous membrane, and has this marked effect on the activity of the pancreatic cells. Involving, as it does, two distinct sets of cells, this chemical adaptation is more complex than any yet investigated, and shows the intimate relation which must exist between the chemical activities of very different organs of the body.

THE ROYAL SOCIETY CONVERSAZIONE.

THE Royal Society conversazione was held in the rooms of the Society at Burlington House on Friday last, May 13. Many exhibits illustrating methods and results of recent scientific progress were on view, and are briefly described in the following abstract of the official catalogue. So far as possible the exhibits representing related subjects are here grouped together.

In the course of the evening, lantern demonstrations were given in the meeting room of the society. Prof. W. A. Herdman gave an account of the recent investigation of the Ceylon pearl fisheries; Mr. Francis Fox showed lantern slides, illustrative of (1) operations at the Simplon Tunnel; (2) the Victoria Falls and gorge of the River Zambesi, and proposed bridge; and the Hon. C. A. Parsons, F.R.S., gave a demonstration of the auxetophone. This instrument is an air operated valve which is used for a reproducer in gramophones and phonographs, and replaces the usual reproducing diaphragm in such machines. The application of this valve to the violin was shown, selections of music, vocal and instrumental, being played on the auxetophone.

The following is a classified list of the other exhibits:—

The differentiator, a machine recording as a curve the values of the rate of change of any variable quantity which can be represented by a curve: Dr. J. Erskine-Murray. When the machine is guided along any curve it automatically traces another which represents the rate of change of the quantity represented by the first curve. Thus, if the population of a country at various dates be plotted on paper the derived curve shows the rate at which the population is increasing or decreasing at every date during the period chosen.—Twin-elliptic figures showing change of phase in one or both ellipses: Mr. Joseph Goold.—A radial area-scale: Mr. R. W. K. Edwards. A contrivance for finding the area of a plane figure by means of a transparency.

Sensitive barograph, for the study of minor variations of atmospheric pressure: Dr. W. N. Shaw, F.R.S. The instrument shows the details of comparatively rapid fluctuations of pressure such as are often indicated in the barometric diagram of the *Times*.—(1) Traces obtained from self-recording instruments sent up by means of kites, (2) self-recording instruments from which the traces were obtained: Mr. W. H. Dines. In the recording instruments designed by M. Teisserenc de Bort, the height is obtained from an exhausted aneroid box, and the temperature from a Bourdon tube. In the recording instruments designed by the exhibitor, the height is obtained from a fair sized aneroid box of thin metal containing air. A temperature correction is necessary, but the position of the pen is dependent on the elasticity of the enclosed air.—Photographs of clouds: Commander D. Wilson-Barker.—Models and photographs of large hailstones: the Royal Meteorological Society.

Photographs and diagrams illustrating solar and meteorological changes, and a series of photographs to determine the relative temperatures of the stars: Sir J. Norman Lockyer, K.C.B., F.R.S. The exhibit illustrated (1) enlarged pictures of the sun in "K" light taken with the spectroheliograph of the Solar Physics Observatory. (2) The results of a discussion of sun-spot distribution. (3) The relationship between the positions of solar prominences and the different forms of the corona. (4) The different types, and their distribution, of the short period barometric pressure variation over the earth's surface. (5) The close connection between the change of barometric pressure and rainfall. (6) Series of photographs taken with a quartz-calcite prismatic camera of 2 inches aperture and 18 inches focal length to determine the relative temperatures of stars.—The Narraburra siderite, New South Wales: Prof. A. Liversidge, F.R.S. This exhibit included photographs of the siderite, and photographs of etched sections to show the changes in the internal structure. The composition of the siderite was:—iron 88·605, nickel 9·741, cobalt 0·474, copper 0·009, phosphorus 0·429, sulphur traces, resinous matter 0·008, insoluble in HCl. 0·720=99·906. Traces of gold and of the platinum metals appeared also to be present.—Transparencies and prints in illustration of a photographic atlas of the heavens; photographed at the Royal Observatory, Cape Town, 1903-4: Mr. J. Franklin-Adams.—Ten transparencies from negatives taken with the Rumford spectroheliograph of the Yerkes Observatory by Prof. G. E. Hale and Mr. F. Ellerman: the Royal Astronomical Society.

Examples showing the application of natural colour photography to the production of lantern slides of spectra for lecture and educational purposes: Mr. E. Sanger-Shepherd. Negatives are taken through three colour filters, admitting light of the three primary colour sensations—red, green and blue-violet, in accordance with the power of the respective sensations to excite the eye. From these negatives gelatin relief prints are made upon a special film, each relief being soaked in a water-colour ink of the complementary colour to the sensation which it represents. These reliefs whilst still wet are successively applied to a mordanted gelatinised glass plate. The inks transfer to the mordanted gelatin film, and the result is a natural colour photograph, consisting of nothing but the colouring matter securely locked up in a single film of gelatin.—Colour photographs shown by spectrum colours: Sir W. de W. Abney, K.C.B., F.R.S. The ordinary three-colour photographs are shown in a triple lantern, one image being tinted by the light coming through red glass, another by that through green glass, and the third by that through blue glass. The new method substitutes spectrum colours for the three glasses, with the result that the colours on the screen are much purer and truer.—High power microscopy: Mr. J. W. Gordon. The apparatus consists of a compounding drawtube and oscillating screen, as proposed in Mr. J. W. Gordon's paper on the Helmholtz

theory of the microscope, recently read before the Royal Microscopical Society. The object exhibited was a diatom (*Pleurosigma angulatum*) magnified about 10,000 diameters.—A cylindrical telescope for the rotation of images: Dr. G. J. Burch, F.R.S. This instrument consists of two cylindrical lenses with their axes of curvature parallel, fixed the sum of their focal lengths apart. Objects seen through it are not magnified, but reversed as by reflection in a mirror. If the telescope is rotated it causes the image to rotate with double the angular velocity.—Large direct vision spectroscope, with ten prisms, automatically adjustable: Mr. P. Heele.—Experiments with non-homocentric pencils: Mr. W. Bennett.—Optical testing bench: Messrs. R. and J. Beck. The bench is so designed that the optical constants of a lens and its various aberrations (chromatic, spherical, astigmatic, &c.) can be rapidly and accurately measured, and is specially adapted for using the new Hartmann system of testing either by direct vision or by photography.—Examples of photomicrography: Mr. Arthur E. Smith and Mr. Richard Kerr.

Some new phosphorescent materials: Mr. H. Jackson. Examples were shown of phosphorescent compounds of zinc, strontium, aluminium, calcium, &c., prepared to illustrate varying degrees of response to such exciting influences as violet and ultra-violet light, electric discharge, heat and friction. By varying the constitution of the compounds in the direction of increasing or diminishing their basic or acidic character the length of time during which the phosphorescent glow lasts can be increased or lessened considerably, and the property of glowing, when heated, can be made to persist apparently indefinitely.—Photographs illustrative of induced radio-activity of bacteria: Dr. Alan B. Green. Small masses of bacterial growth were exposed to the β and γ rays of 10 mg. of virtually pure radium bromide. In a large number of instances such masses when removed from the influence of the radium and placed between two thin sheets of glass, themselves not radio-active, were capable of so affecting the sensitised film of a photographic plate with which they were brought in contact, that on development in the ordinary way, the plate showed a dark area corresponding to the shape of the bacterial mass. The photo-actinic rays proceeding from the bacteria which had been exposed to radium were capable of affecting a photographic plate through a double layer of lead foil.

A method of mechanically reinforcing sounds: Mr. T. C. Porter. An ordinary "Home" Edison-Bell phonograph with the "reproducer" is used as the source of the sounds. In this instrument the roughness of the record makes a rod vibrate, and these vibrations are communicated mechanically to a thin disc of glass or mica, which in turn transmits them to the air on the side of the disc remote from the rod; the aërial disturbances are then conducted by a tube usually to a trumpet, but in this experiment the reinforcement of the sounds is obtained by the combustion of coal-gas and air. The mixed gases are led over the disc of the "reproducer" and conveyed by tubing to two convergent jets and then ignited. A further reinforcement is obtained by placing platinum foil in the flame.—Experiments on lubrication showing cavitation: Mr. S. Skinner. The lubricating fluid in the space, between a bearing and the axle working in it, is subject to conditions in which cavitation, *i.e.* the formation of vacuous spaces in the fluid, can occur. This was shown by a series of experiments, in which the deeply coloured lubricating fluid is contained between glass surfaces, and light is transmitted through the cavities.—(1) Microphone-buzzer (with partially tuned telephone) giving a nearly pure note of 2000 vibrations per second; (2) apparatus used to investigate the distribution of temperature in the field coils of electric machinery; (3) apparatus for rapid electric thermometry: the National Physical Laboratory.—(1) Vibrograph for recording vibrations photographically; (2) micro-manometer: the Cambridge Scientific Instrument Company, Ltd.—Stream gauge for indicating the rate of delivery of air or gas by a pipe: Mr. R. Threlfall, F.R.S.—(1) Stereoscopic views and specimens illustrating the construction of the Simplon Tunnel; (2) stereoscopic and other views of the Victoria Falls of the River Zambesi: Mr. Francis Fox.

Apparatus for the metrical study of stationary electric waves on spiral wires: Prof. J. A. Fleming, F.R.S. The apparatus exhibited consists of a long solenoid of silk-covered wire having 5000 turns and a total length of 643 metres. This solenoid has parallel to it an adjustable earth wire and a divided scale. The solenoid is connected to one point on an oscillatory electric circuit consisting of a couple of Leydens having a capacity of 0·00068 mfd. and an adjustable inductance of 0 to 230 microhenrys and a silent discharger. When oscillations are set up in this circuit by induction coil discharges and the frequency adjusted, stationary electric waves are set up in the solenoid. The position of the loops and nodes is ascertained by the use of a series of carbonic dioxide vacuum tubes.—Edison's secondary battery (or accumulator) for automobiles: Mr. W. Hibbert and Mr. H. E. Dick.—Electrical instruments of precision: Colonel R. E. Crompton, C.B.—Improved muffle and melting furnaces for use in laboratories or art studios: Mr. H. H. Cunynghame, C.B. The plan on which these furnaces are constructed is to jacket them thickly with non-conducting material, in such a way that heat cannot escape as fast as it is developed, until a high temperature has been attained.—Electric resistance furnaces for laboratory use: Mr. Bertram Blount.

Specimens illustrating the action that occurs between metals at a temperature many hundreds of degrees below their melting point: Mr. Sherard Cowper-Coles.—Apparatus for determining the ignition point of gases: Prof. H. B. Dixon, F.R.S., and Mr. G. W. A. Foster.—Specimens of methyl and other derivatives of sulphur, selenium and tellurium: Dr. A. Scott, F.R.S.

(1) A new natural order of plants, the Amphipterygiaceæ, Hemsley and Rose; (2) fruits of *Melocanna bambusoides*, an exalbuminous, viviparous bamboo; (3) *Hydnophytum longifolium* (Rubiaceæ), Fiji Islands; (4) *Dischidia rafflesiana* (Asclepiadaceæ), Malaya; (5) *Aspidium anomalum*, Ceylon: the Director, Royal Botanic Gardens, Kew.—(1) Specimens illustrative of cotton cultivation in British colonies and dependencies; (2) map showing the "cotton belt" and the British and foreign areas in which cotton is now commercially or experimentally cultivated (from Prof. Dunstan's report on cotton cultivation in the British Empire and Egypt); (3) mineral and rock specimens from Ceylon and southern Nigeria; (4) specimens of the seeds of *Hevea brasiliensis* (Para rubber tree) from the Straits Settlements: Prof. Wyndham R. Dunstan, F.R.S., director of the Imperial Institute.—Microscopic slides illustrating nuclear division in cells of malignant growths of man: Prof. J. B. Farmer, F.R.S., Mr. J. E. S. Moore and Mr. C. E. Walker.—Microscopic preparations illustrating the parasitism of the rust fungi or Uredineæ: Prof. H. Marshall Ward, F.R.S.—Microscopical preparations to show the fertilisation and alternation of generations in the Uredineæ: Mr. V. H. Blackman.—Plants and photographs from the High Andes of Bolivia and Peru: Mr. A. W. Hill.—A series of hybrid wheats illustrating Mendel's laws: Mr. R. H. Biffen.

The pearl-oyster fisheries of Ceylon: Prof. W. A. Herdman, F.R.S.—Microscopical preparations and diagrams of the chromatophores of the higher Crustacea: Mr. Frederick Keeble and Mr. F. W. Gamble. The coloration of such Crustacea as *Hippolyte varians* is due to pigments contained in chromatophores. The chromatophores consist of several compartments, in each of which a single pigment is present. When contracted to the centre of the chromatophore, a pigment plays no part in the coloration of the animal; when expanded into the superficial network which communicates with the centre, the pigment takes a share in the coloration.—Ticks and tick-transmitted diseases: Dr. G. H. F. Nuttall, F.R.S. The exhibit included specimens of ticks which transmit several diseases; also specimens of the parasites and figures.—Nematocysts of Æolids: Mr. G. H. Grosvenor.—International North Sea investigations. Results of work during 1903, from the Plymouth and Lowestoft laboratories: the Marine Biological Association.

A photographic study of the English skull, 1600–1850: Prof. Karl Pearson, F.R.S. The photographs of English skulls illustrated normal and abnormal types. There were two series, numbering upwards of 500 altogether, from old plague pits or graveyards in the City of London. Both series were of great interest, and the nearest related group to one of them appears to be long barrow British.—Apparatus and methods employed for measuring, in the

case of human blood, its content in agglutinating substances, bactericidal substances, red blood corpuscles, albuminous substances, calcium salts, and salts generally: Dr. A. E. Wright.—(1) Wax model of the marmoset's brain; (2) sections from which the wax model was constructed: Mr. Gustav Mann.

(1) Colour printed geological maps; (2) geological model of the Isle of Purbeck: the director of the Geological Survey and Museum.—Models illustrative of mountain building: Lord Avebury, F.R.S.—(1) A set of lantern slides of microscopic sections of igneous rocks, &c.; (2) portable sounding machine for mountain lakes: Prof. E. J. Garwood. —Series of geological and other drawings and plans: Prof. J. P. O'Reilly.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—In connection with the approaching international assembly of representatives of academies, it is proposed to confer the degree of Doctor of Science *honoris causa* on Prof. Bakhuyzen, of Leyden; Dr. Faminstyn, of St. Petersburg; Dr. Mojsisovics von Mojsvár, of Vienna; Prof. Retzius, of Stockholm; Prof. Riecke, of Göttingen; and Prof. Waldeyer, of Berlin; and the degree of Doctor of Letters *honoris causa* on Count de Franqueville, of Paris; Prof. Goldziher, of Budapest; Prof. Gomperz, of Vienna; Prof. Krumbacher, of Munich; Prof. Leroy-Beaulieu, of Paris; and Dr. Perrot, of Paris.

Mr. W. J. Sell, F.R.S., and Mr. H. J. H. Fenton, F.R.S., are to be appointed university lecturers in chemistry, and Mr. A. Harker, F.R.S., a university lecturer in petrology.

The Senate of the Royal University of Ireland has resolved to confer, *honoris causa*, the degree of Doctor of Science on Sir William Crookes and on Prof. J. Dewar.

Science states that the New York University has received an anonymous gift of 2500*l.* for the Medical College, and that the American Geographical Society has received a bequest of 6000*l.* from Sarah M. de Vaugrigneuse.

In a paper on "Local Expenditure and Local Indebtedness in England and Wales," read by Mr. R. J. Thompson at the Royal Statistical Society on Tuesday, it was stated that education showed an increase of expenditure from 4,806,000*l.* in 1889 to a sum of nearly 11,000,000*l.* in 1902. The cost of erecting school buildings had during the same time—1889 onwards—augmented the outstanding loans from 9,937,000*l.* to 33,564,000*l.* London incurred 29 per cent. of the total expenditure, while it contributed only one-fifth of the total number of pupils.

The inauguration on February 10 of an information bureau in connection with the University of Paris is an excellent innovation. The bureau will afford information on all matters connected with higher education in Paris, whether in Government or private institutions. Those who in this country are contemplating entering a university, and who have spent hours in trying to derive some tangible ideas from calendars and class syllabuses, will appreciate the useful purpose which would be served by a bureau of this character. If such a bureau would go a little further, and furnish to candidates for chairs and lectureships some idea of the duties they would have to perform, its value will be still greater.

The President of the Board of Education, the Marquess of Londonderry, K.G., has appointed a departmental committee to inquire into the present working of the Royal College of Science, including the School of Mines, to consider in what manner the staff, together with the buildings and appliances now in occupation or in course of construction, may be utilised to the fullest extent for the promotion of higher scientific studies in connection with the work of existing or projected institutions for instruction of the same character in the metropolis or elsewhere, and to report on any changes which may be desirable in order to carry out such recommendations as they may make. Sir Francis Mowatt, G.C.B., is chairman of the committee, and Mr. J. C. G. Sykes, assistant secretary in the branch of the board which deals with evening schools, technology, and higher education in science and art, has been appointed secretary to the committee. The London County Council is represented on the committee.

A deputation consisting of representatives of various county councils was received by Sir William Anson on May 13 with reference to the abrogation of the arrangements which were in vogue under what was known as Clause 7 of the Directory of the Science and Art Department. The deputation explained that county councils had hoped when the Education Act became law that it would be recognised more fully than before that these councils were the authorities for all grades of education, including particularly higher education. But the new regulations taking the place of Clause 7 have reduced their powers, and county councils are hampered in the performance of the duties expected of them. In reply, Sir William Anson explained that Clause 7 was an attempt to bring local authorities into relations with the efforts being made to give science and art and technical teaching, assisted by the Board of Education, and limited in the first instance to institutions of a very different character from ordinary secondary schools. Local authorities are now in a position to deal with the whole of secondary education, and not merely with the subject-matter which was contemplated in Regulation 7. Sir William Anson, in conclusion, asked the deputation to consider the wider question which they should have in view in dealing with secondary education, and not merely from the point of view of exercising their own authority and the speedy transaction of their own business. What he deprecated was that at that early stage in the working of the Act, the Board of Education should be asked to stereotype the relations of local authorities for the secondary schools within their area.

At the annual conversazione of the Medical Society of London on Monday, Sir Isambard Owen delivered the annual oration, taking for his subject "The Future of London Medical Education." After contrasting the interest displayed by Continental States in scientific research and public education with the indifference evinced towards them by the generality of Englishmen, and pointing out that this indifference could only be a passing phase, due to patent historical causes, he expressed the hope that the reports of the Mosely Commissioners, with their marvellous tale of recent educational progress in America and the fabulous amounts of public and private money freely lavished upon it, would at last awaken attention here to the backward state of things at the heart of the British Empire. Of all forms of higher education, he submitted, none could lay greater claim to public support than medical education. The unendowed London schools had still to carry the entire burden of the preliminary academic training of their students—a task which elsewhere was now undertaken by endowed universities and university colleges. Until the reconstitution of the University of London, no practicable way out of the difficulty could be seen. Sir Isambard Owen then detailed the plan which the university had adopted of establishing a public institute within its bounds and under its direct control to undertake teaching in physics, chemistry, biology, anatomy, and physiology for the purposes of medical students. Including buildings, the institute would cost about 375,000*l.* to establish. As the State declined all responsibility for professional education in England, the university could only look to enlightened private liberality. Wealthy men in London capable of being fired by emulation of Transatlantic gifts to education should make this modest benefaction their peculiar care.

SOCIETIES AND ACADEMIES.

London.

Anthropological Institute, April 26.—Sir Thomas Holdich, K.C.M.G., &c., in the chair.—Prof. W. **Ridgeway** delivered a lecture on the origin of jewellery. Prof. Ridgeway holds that the objects employed in modern jewellery had their origin in magical properties attributed to them and not in æsthetic, although the æsthetic reason for wearing them undoubtedly influenced the wearers at an early stage (see Nature, October 29, 1903, vol. lxviii. p. 636).

Challenger Society, April 27.—Sir John Murray in the chair.—Prof. **Minchin** exhibited specimens of the new sporozoan, *Lymphocystis johnstoni*.—Mr. E. T. **Browne** showed Medusæ from Valencia.—Dr. G. H. **Fowler** explained some graphic diagrams of the distribution of Biscayan Chætognatha, and announced that he had detected *Krohnia hamata* among specimens obtained at the Falkland Islands by Mr. Vallentin within six fathoms from the surface.—Mr. V. H. **Blackman** read a paper on the metabolism of the ocean, dealing with the close analogy between the circulation of nitrogen on land and that in the sea; this was followed by an interesting discussion.—Mr. G. P. **Farran** described the copepods of the north-east Atlantic slope; of these rather less than half present a wide and often tropical distribution, occurring also in the Indian or Pacific Oceans. The remainder are only known as Atlantic or Atlanto-Mediterranean species, many being bottom haunting forms, the recorded range of which is likely to be extended. About 12 per cent. of the total copepod fauna extends north to the Arctic regions.

British Academy, April 27.—Lord Reay, president, in the chair.—Prof. I. **Gollancz** read a paper on Shakespeariana, 1598–1602. A theory was put forward explanatory of Shakespeare's use of the name Polonius for the counsellor of the King of Denmark in place of Corambis, or Corambus, found in the first quarto, evidently the name of the character in the old play, which belonged to about the year 1587. Corambus, being discarded by Shakespeare, was used by him as a passing name in the play of "All's Well."

Physical Society, May 6.—Mr. J. Swinburne, vice-president, in the chair.—Some instruments for the measurement of large and small alternating currents: W. **Duddell**. The author, after some preliminary remarks on the available means for measuring alternating currents, proceeded to describe three thermal instruments which he has constructed for this purpose. The first instrument is essentially a sensitive Ayrton-Perry twisted strip ammeter which is very quick in action for a thermal instrument, and has been used for observing and recording P.D.'s and currents which varied as rapidly as one per second. The second instrument exhibited was a very sensitive thermal galvanometer called in the paper a "thermogalvanometer." It consists of the combination of a radio-micrometer of the "Boys" type with a very small resistance which is heated by the current to be measured, and in turn heats the thermojunction of the radio-micrometer by radiation and convection. The third instrument described was a switchboard instrument which works on the same principle as the last.—Mr. F. E. **Smith** exhibited and described the following instruments from the National Physical Laboratory:—(1) a mercury-resistance standard; (2) a 10-ohm build-up resistance-box; (3) an astatic galvanometer.

Mathematical Society, May 12.—Dr. E. W. Hobson, vice-president, in the chair.—The following papers were communicated:—On the evaluation of certain definite integrals by means of Gamma functions, and generalisations of Legendre's formula $KE'-(K-E)K'=\frac{1}{2}\pi$: A. L. **Dixon**. It has been shown by E. B. Elliott that Legendre's relation may be regarded as a particular case of a relation by which a certain sum of products of what are really hypergeometric functions can be expressed in terms of Gamma functions. In the Weierstrassian form of Legendre's relation, a certain determinant of the second order having elliptic integrals as its elements is shown to be a constant. In the generalisation the determinant is of order higher than the second, the elements are hyperelliptic integrals, and the constant is expressed as a product of Gamma functions. The ratio of two such determinants, of suitable orders, is expressed in a similar form. Weierstrass's relations between hyperelliptic integrals of the first and second kinds are deduced. The results are extended to include a certain class of integrals which are not integrals of algebraic functions.—Perpetuant syzygies: A. **Young** and P. W. **Wood**. The perpetuants considered are linear in the coefficients of each quantic concerned, that is to say, they are "perpetuant types." All possible products of irreducible forms of a given degree and weight are arranged in a predetermined sequence so that any product may be identified by its place in the sequence. A syzygy expresses one of the products that enters into it, viz. the one that comes earliest in the sequence, in terms of others which come later in the sequence. In consequence of the existence of the syzygy this earliest product is "reducible." It is possible to enumerate the actually irreducible forms for degree δ by means of a generating function. When the irreducible products have been identified for any degree, all the independent syzygies of this degree will have been identified, there being one such syzygy for each reducible product of irreducible forms. The work can be completed as far as degree 8, but a large class of products have been discussed in general. A generating function for all irreducible products and types of degree δ is suggested in the form

$$\frac{x^{\binom{\delta}{1}+\binom{\delta}{2}+\cdots+\binom{\delta}{\kappa}}}{(1-x)^{\delta-1}}$$

and this form is proved to hold for $\kappa=1$, $\kappa=2$ and $\kappa \geq \frac{1}{3}\delta$.—Note on the integration of linear differential equations: Dr. H. F. **Baker**.—Some properties of the function Γ_p: **Rev.** F. H. **Jackson**.—Informal communications were made as follows:—On the geometrical representation of imaginaries: G. B. **Mathews**.—A collation of Kessler's and Hertzer's tables of the residue-index (ν) of 10 (mod p) with Shanks's table of the Haupt exponent (ξ) of 10 (mod p): Lieut.-Colonel A. **Cunningham**. The numbers ν and ξ are defined by the congruence $10^{\xi}\equiv 1$ (mod $p=\nu\xi+1$). Twenty-nine errors were found in Kessler's table, 3 in Hertzer's, 107 in Shanks's.

CAMBRIDGE.

Philosophical Society, May 2.—Dr. Baker, president, in the chair.—Early development of the unfertilised egg of the sawfly *Nematus ribesii*: L. **Doncaster**. In the unfertilised egg the two maturation divisions give rise to four nuclei, the outer two of which are the halves of the first polar body, the third is the second polar nucleus, and the innermost the egg-nucleus. The second polar nucleus unites with the inner half of the first, giving the "copulation nucleus." This divides into two groups of chromosomes, which persist without important change until the blastoderm begins to form, beyond which stage their fate has not yet been followed. The egg-nucleus soon begins to divide, and gives rise to the embryo, the chromosomes remaining at the reduced number. The outer nucleus of the first polar body rapidly disappears. These results are very similar to those obtained by Petrunkewitsch in the bee, where, as in this case, virgin eggs produce males, and fertilised eggs females. It was pointed out that a comparative study of the development of sawflies which produce males and females respectively from virgin eggs would provide a test of Castle's hypothesis of sex-determination.—Metallic "passivity" in relation to time and temperature: Dr. W. A. **Hollis**.—(1) On partial fractions; (2) note on plane unicursal curves; (3) on the order of certain systems of conditions: Dr. A. C. **Dixon**.

PARIS.

Academy of Sciences, May 9.—M. Mascart in the chair.—The president announced to the academy the death of M. Duclaux, member of the section of rural economy, and gave a short account of his life work.—Remarks on the use of alternating currents in chemistry and on the theory of reactions which they set up: M. **Berthelot**. Remarks on the recent work of MM. Brochet and Petit concerning the solution of platinum in a solution of potassium cyanide by the action of an alternating current. The author directs attention to a similar reaction with glucose studied by him in 1879. The bearing of these experiments on the action of the silent discharge is also discussed.—The cooling power of a feebly conducting liquid current on an indefinite cylinder, the axis of which is normal to the current: J. **Boussinesq**.—On a new method of preparation of alkyl and alkylidene derivatives of cyclic ketones. The application to the preparation of alkyl-menthones: A. **Haller**. By treating certain cyclic ketones, such as menthone, with sodium, the corresponding alcohol is formed besides the sodium derivative, and in preparing alkyl derivatives this leads to undesirable secondary products. The formation of the alcohol is avoided if sodium amide is used instead of sodium, and the

alkyl iodide can be added directly to the reaction product. The physical properties of several homologues of menthone which have been prepared in this way are described.—An arrangement allowing identical results to be obtained with X-ray tubes on different occasions: M. **d'Arsonval.** The current passing through the tube is measured by means of a milliammeter of the d'Arsonval type. For a tube with a given vacuum, the amount of X-rays given off, as measured by their photographic effect, is proportional to the intensity of the current passing through the tube, and this appears to be true of various makes of tube.—M. Barrois was elected a member in the section of mineralogy in the place of the late M. Fouqué.—Observations of the Brooks comet (1904 *a*) made at the Observatory of Algiers with the 31·8 cm. bent equatorial: MM. **Rambaud** and **Sy.**—The linear *connexe* in space of $n-1$ dimensions: Léon **Autonne.**—On the radio-activity of gases given off from the water of thermal springs: P. **Curie** and A. **Laborde.** The radio-activity of samples of gas from various mineral waters was measured and its rate of decay determined, the results being compared with the radio-activity of air which had been in contact with a known amount of radium bromide. The radio-activity was in all cases very small, and it hardly appears possible to draw any conclusion as to the action the radio-activity may play in the physiological actions of mineral waters.—On the melting point of gold: Daniel **Berthelot.** It is pointed out that all the recent values for the melting point of gold fall between 1064° and 1067°.—On the fixity of the solar rays: Maurice **Hamy.** The author has previously shown that there is a slight variation in the wave-length of the λ 508 cadmium ray according as a tube with or without electrodes is employed. Since the physical conditions in the sun are liable to considerable variation at times, the question is raised as to how far the solar lines can be regarded as possessing absolutely fixed wave-lengths.—The proof of a radio-activity induced on all bodies by the emanation from incandescent metallic wires: Th. **Tommasina.**—The action of anæsthetics on the sources of the *n*-rays: Jean **Becquerel.**—On some points of technique for the examination of organs by means of the *n*-rays. First results relating to a study of the brain: André **Broca.**—On the mode of propagation of nervous oscillations: Augustin **Charpentier.**—Electrical osmosis in methyl alcohol: A. **Baudouin.**—On the atomic weight of samarium: G. **Urbain** and H. **Lacombe.** The samarium salts were obtained from three different sources, and atomic weight determinations of the various fractions, together with the spectroscopical examination, showed that the oxide was homogeneous. The final value for the atomic weight of samarium (O=16) is 150·34.—The formation of hydrogen silicide by direct synthesis from its elements: Ém. **Vigouroux.** Remarks on a recent paper by M. Dufour on the same subject.—The apparent volatilisation of silicon in hydrogen: A. **Dufour.** In Geissler tubes filled with hydrogen arsenide, the arsenic deposited by the discharge is displaced by distillation pure and simple; in tubes filled with hydrogen silicide, the displacement of the silicon under similar conditions is explained by the formation of hydrogen silicide in the warm parts of the tube and its decomposition in the dark space.—On a property of tin-aluminium alloys: Hector **Pécheux.**—The differentiation of the primary, secondary and tertiary alcohols of the fatty series: André **Kling** and Marcel **Viard.** The method adopted is based on the fact that tertiary alcohols are decomposed at the temperature of boiling naphthaline, whilst at the temperature of boiling anthracene only primary alcohols resist decomposition. The vapour density of the alcohol under examination is taken in a Victor Meyer apparatus with the above two liquids as vapour jackets, the deviation from the theoretical density showing to which class the alcohol belongs. About 250 determinations have been made by this method, a summary of which is given.—On the formation of the chloroanilines: Eyvind **Bœdtker.**—On the saponifying power of the castor oil seed: Maurice **Nicloux.**—On the structure of the heart in Cephalopods: F. **Marceau.**—The resistance of certain seeds to the action of absolute alcohol: Paul **Becquerel.** The tegument of the moist grain allowing of osmosis is permeable to absolute alcohol, but when dried to a certain extent, osmosis no longer takes place, and the skin is now absolutely impermeable to alcohol.

DIARY OF SOCIETIES.

THURSDAY, May 19.

Royal Society, at 4.30.—The Bakerian Lecture will be delivered by Prof. E. Rutherford, F.R.S., on the Succession of Changes in Radio-active Bodies.—The following papers will be read in title:—The Spectrum of the Emanation of Radium: Sir William Ramsay, K.C.B., F.R.S.—On Saturated Solutions: Earl of Berkeley.—On the Liquefied Hydrides of Phosphorus, Sulphur, and the Halogens, as Conducting Solvents. Part i.: B. D. Steele and D. McIntosh.—On the Liquefied Hydrides of Phosphorus, Sulphur, and the Halogens, as Conducting Solvents. Part ii.: D. McIntosh and E. H. Archibald.—On the General Theory of Integration: Dr. W. H. Young.

Institution of Mining and Metallurgy, at 8.—Miners' Phthisis—its Causes and Prevention: Dr. J. S. Haldane and R. A. Thomas.

Institution of Electrical Engineers, at 8.—Discussion on Messrs. Parsons, Stoney and Martin's paper, entitled The Steam Turbine as applied to Electrical Engineering.

FRIDAY, May 20.

Royal Institution, at 9.—The Radiation and Emanation from Radium: Prof. E. Rutherford, F.R.S.

TUESDAY, May 24.

Royal Institution, at 5.—The Solar Corona: H. F. Newall, F.R.S.

Linnean Society, at 8.—Anniversary Meeting.

WEDNESDAY, May 25.

Geological Society, at 8.—Occurrence of a Limestone with Upper Gault Fossils at Barnwell, near Cambridge: W. G. Fearnsides.—Age of the Llyn-Padarn Dykes: J. V. Elsden.

Victoria Institute, at 4.30.—The Tanganyika Problem: W. H. Hudleston, F.R.S.

THURSDAY, May 26.

Royal Institution, at 5.—Literature and the State: H. G. Wells.

Institution of Electrical Engineers, at 8.—Annual General Meeting.

FRIDAY, May 27.

Royal Institution, at 9.—The Progress of Oceanography: H.S.H. Albert Prince of Monaco.

Physical Society, at 5.—The Law of Action between Magnets and its bearing on the Determination of the Horizontal Component of the Earth's Magnetic Field with Unifilar Magnetometers: Dr. C. Chree, F.R.S.—On the Ascertained Absence of Effects of Motion through the Ether in Relation to the Constitution of Matter on the FitzGerald-Lorentz Hypothesis: Prof. J. Larmor, Sec.R.S.—On Coherence and Recoherence: Dr. P. E. Shaw and C. A. B. Garrett.

SATURDAY, May 28.

Royal Institution, at 3.—Spitsbergen in the 17th Century: Sir W. Martin Conway.

THURSDAY, MAY 26, 1904.

STEPS TOWARDS A NEW PRINCIPIA.

Electricity and Matter. By Prof. J. J. Thomson. Pp. 162; with diagrams. (Westminster: Archibald Constable and Co., Ltd., 1904.) Price 5*s.* net.

IT is an interesting fact that the British Association is going so soon to meet, under distinguished presidency, at Cambridge, for there of late years has the most splendid work in pure physical science been done, and there it seems to me an erection comparable in some respects to the Principia is being raised. One of the foundation stones was laid in 1881 by J. J. Thomson in a mathematical paper on the motion of a charged sphere, a paper in which the idea of real electric inertia took tangible and tractable form. The building has been growing ever since, and is now in full process of construction, though I hope it will be long before its development shall cease or the work be regarded as finished and ready to be left to the admiration of future generations.

The little book which constitutes the subject-matter of this review embodies a set of six lectures delivered on the other side of the Atlantic, at the invitation of Yale University, last spring, by the Cavendish professor of physics at Cambridge, England.

They are not exactly popular, for although no mathematics is introduced beyond what ought to be (but usually is not) familiar to all who have been in the sixth form at a public school, yet the ideas are definite and quantitative, and are briefly expressed because they are addressed to persons with some knowledge of physics; moreover, they are such as can hardly be made so childishly simple as to be apprehended of the general average of so-called educated men in this country, whose sense-perceptions in the direction of great and comprehensive ideas have not been developed.

To students of physics and higher chemistry this book serves as a very readable digest and summary of what is to be found worked out in more detail in other writings by the same author; and those who have studied his most recent papers can hardly avoid reading back into this little volume, which can be skimmed at a sitting, much that has really been elaborated since, and some things which still await elaboration, on lines which are merely suggested here.

It is difficult to exaggerate the suggestiveness of the wealth of theory which is now being lavished upon us in the domain of atomic structure and the mathematics of chemistry; it appears likely to lead to a definite microcosmic astronomy, based upon the known properties of electric lines of force, akin to the welding together of the observed facts of the heavens by a single comprehensive law, and forming the basis of a real chemical "Principia."

The discovery on which everything depends is the recognition of the atom of electricity, a discovery to which no one man can lay claim, and superposed upon this a detection of the extraordinary properties belonging to an electric line of force, at rest, in motion, and under acceleration, which is again a development to which several have contributed. But it is safe to say that a great bulk of the treatment of the subject, both on its experimental and mathematical side, emanates, with a few important exceptions, in some form or other from Cambridge, and it is difficult to overestimate the force and suggestiveness with which ideas connected with the most recent and still nascent steps in theory are presented in this small book.

The book is in six chapters, corresponding apparently with six lectures.

Chapter iv., on the atomic structure of electricity, gives the customary account of the evidence for electric atoms, and for considering the charge on a corpuscle to be identical with the ionic charge of a hydrogen atom; the experiments by which these conclusions were reached in the Cavendish Laboratory being summarised and explained on the usual lines. First, it was shown that the conductivity of a gas depended on something that could be filtered out of it; next, the aggregate charge of the ions in a given volume of gas was determined by the method of the saturation current; then these ions were counted by the highly ingenious "cloud" method, and thus the charge on each determined. The value, it may be noted in passing, is rather higher than what used to be roughly estimated for this fundamental electric unit. Whereas it used to be guessed as about 10^{-11} electrostatic units, measurement seems to show that it is more nearly 3.4×10^{-10}; and, in order to make this quantity equal to the charge on a monad ion in electrolysis, the number of molecules in a cubic centimetre of gas, at standard temperature and pressure, must be rather fewer than used to be estimated as probable, and also rather definite, being about 3.6×10^{19}, which means 8×10^{23} atoms of hydrogen per gram.

A new confirmatory method applied by Dr. H. A. Wilson is described, in which the settling of a cloud under gravity is opposed by a measured electric field; and on this plan the same result is obtained. Also Prof. Townsend and Dr. H. A. Wilson, by applying electrolytic considerations and experiments to ionised air, were able to show directly that the ionic charges in all cases are really identical, and are the same as that familiar in electrolysis.

A rapid summary of the now well known methods by which the mass of the carriers for negative and for positive electricity respectively has been determined is also given, and it is pointed out how striking is the resemblance of the result to Franklin's one-fluid theory of electricity:—

"The 'electric fluid' of Franklin corresponds to an assemblage of corpuscles, negative electrification being a collection of these corpuscles. The transference of electrification from one place to another is effected by the motion of corpuscles from the place where there is a gain of positive electrification to the place where there is a gain of negative. A positively electrified body is one that has lost some of its corpuscles. We have seen that the mass and charge of the corpuscles have been determined directly by experiment. We in fact know more about the 'electric fluid' than we know about such fluids as air or water."

The next chapter (v.), on the constitution of the atom, begins still on familiar ground, and exhibits the evidence for the great intrinsic energy of electrically constituted atoms, and estimates the rate of radiation of energy from corpuscles variously distributed inside an atom, showing that the radiation from a single corpuscle is far greater than that to be expected from two or more, especially when their speeds are not excessive. [It may be observed that a pair of revolving electrons, at opposite ends of a diameter, will be equivalent to two equal opposite currents, and hence will tend to neutralise each other's influence at a distance, especially along the axis of revolution; unless indeed they are moving with the speed of light, in which case they could start the crest and trough of an advancing elliptically-polarised wave.] Hence a certain number of corpuscles are essential to the stability of an atom, a few would soon radiate their energy away; and this fact, on the doctrine of the evolution of matter, suggests a reason for the non-existence of permanent elements of lower atomic weight than hydrogen.

But a great deal more than that is made out towards the end of the chapter, where the electric constitution of the atom is applied to chemistry, and a beginning of the explanation of "the periodic law" is made in this chapter which is further developed by the author in a great paper in the March number of the *Philosophical Magazine* for the present year. Also the homologous series of lines in the spectrum, investigated by Rydberg, Runge and Paschen, and Kayser, is shown to be a fairly natural, or at least plausible, consequence of the groupings of various numbers of corpuscles or electrons inside an atom; though it must be admitted that unless attention is paid to the modern view that concussions and not regular motions are the real cause of perceptible visible radiation and line spectra, the theory remains obviously very incomplete. The mode in which the corpuscles would statically distribute themselves, if they were limited to a plane, under the combined action of a mutual inverse square repelling force and a direct-distance central attracting force, is treated much as Lord Kelvin had already treated it in his remarkable paper called "Æpinus atomized" (reprinted as an appendix in his Baltimore Lectures), and is illustrated by Alfred Mayer's experiments on floating magnets; and the deductions, although plainly only the nucleus of an investigation, are already very suggestive and promising. In the March *Philosophical Magazine* the investigation into the stability of moving electrons is carried much further, and a distinct step is made in mathematical chemistry.

One very simple and important remark is made near the end of chapter v. concerning the "bonds" of the chemist, which, being I suppose universally recognised as Faraday lines of electric force, must differ from ordinary stretched elastics in having opposite properties at the two ends. The bonds, in fact, must have "sense" as well as direction, they are not simple links; and hence when carbon atoms are linked together those atoms cannot really have identical properties, unless indeed they are linked to each other by an even number of bonds. Incidentally it becomes clear at any rate in the March *Phil Mag.* it becomes clear to me—why carbon or tetrad atoms can link themselves into complex molecules: the foundation of organic chemistry.

A suggestion is also made concerning certain "additive" properties, such as the refractive power of different substances for light, which students of physical chemistry will do well to take up and press further.

The obvious question as to how an electrically constituted atom can acquire an additional charge, so as to become an ion, either positive or negative, and either monad, dyad, or triad, is discussed, and a guess is made as to the nature of molecular combination. It is also attempted to explain why a liquid, say liquid mercury, is so immensely better a conductor than mercury vapour, and why some gases may be conductors and others not. The violent motion of corpuscles going on inside an atom is styled by J. J. Thomson the "corpuscular temperature" of the atom, which may or may not be a convenient term; the ordinary temperature of the gas, called "molecular temperature," is generally very much smaller, and has no apparent relation with the corpuscular temperature. By the interaction of these two temperatures on one another, an attempt is made to account for certain chemical facts of combination. The whole of the chapter is so concentrated and full of suggestion that it is impossible effectively to abstract it further. What I wish to indicate to students is the desirability of studying the original.

Prof. Poynting has on this point made a remark to me which he permits me to incorporate, viz., that at high molecular temperatures there must be some distinct correspondence between molecular and corpuscular temperatures. For in the sun corpuscles are set free by collisions [as they may also be set free by the clash of chemical combination at more ordinary temperatures, a bright line spectrum resulting in both cases from the perturbation of those corpuscles which, although shocked, escape separation]. There would appear to be some high temperature at which the atoms go to pieces—a limiting molecular temperature beyond which they cannot exist (an atomic dissociation temperature), not *much* higher probably than the solar temperature. It is worthy of remark that no star is much hotter than the sun: possibly none so high as ten thousand degrees centigrade. If not, why not? unless it be because there is a natural limit at which matter goes to pieces.

The final chapter, on radio-activity and radio-active substances, emphasises the way in which atomic collapse, or re-distribution of corpuscles—a sort of atomic earthquake—may occasionally occur, after the radiation of a certain amount of energy has gone on for some time, by spontaneous re-arrangement of the constituents into a more stable form. For since orbital motion plainly tends to increase stability, enabling a greater number of corpuscles to resist central attraction than could hold out if they were stationary, it follows that, as the corpuscles slow down, they may at certain critical stages find it necessary to fall into

an allotropic modification of the element, or else to expel some and re-arrange the remainder; the analogy being a spinning top which tumbles over when its velocity falls below a certain critical value. [Some varieties of "new star" may conceivably furnish another and different kind of analogy.]

A new suggestion also is made with respect to Röntgen rays, viz. that they may sometimes precipitate atomic disintegration and thus cause a substance to emit more energy than they themselves contain. It is also pointed out in a previous chapter how a shell of Röntgen radiation will not disturb particles over which it passes if it is below a certain thickness, but if thicker than that will communicate momentum to them; and in that way a kind of modified Le Sage's gravitation hypothesis is suggested, not, however, in a convincing manner, but rather as one of the possibilities that have to be discussed, and after further consideration probably abandoned. At the same time, the hypothesis concerning radium favoured by Lord Kelvin, viz. the reception of energy from a store of cosmic waves and the consequent production of radioactivity, is shown to be in many respects feasible, though taken all round unlikely and rather artificial.

But the most remarkable and novel portion of the book is the use made of Faraday's lines of force, and the great development and importance attached to them, in the first three chapters. Strangely enough, these lines are for the first time regarded as realities; no longer as a mere map of a state of things which is essentially continuous, but as an actual fibrous structure attributable to an electric field, and therefore also to a magnetic field, and therefore also to radiation. The lines of force are not only *like* elastic threads which repel each other, but really are such threads, though with varying thickness and with their tension everywhere proportional to their cross-section; and it seems possible to think of them as vortex filaments, thus reproducing in many respects FitzGerald's conception of a fibrous vortex ether consisting of filamental or cobweb vortices interlaced in every direction (see preface to "Modern Views of Electricity," 1889), only these do not become lines of force unless they are cut and terminated; the newer view regards the place where their intense ends terminate as a negatively charged corpuscle or electron, their wider opposite ends appearing to correspond with positive electricity, the nature of which, however, still remains a close secret. This seems to be J. J. Thomson's view—though it is not clear that he regards the vorticity as anything more than an analogy his view is that the lines of force or vortex fibres actually exist, radiating from corpuscles, constituting electric lines of force, generating magnetic fields when they move, and conferring mass on the particle by reason of the amount of ether entangled inextricably in each filament; and he shows further how, when the fibres are accelerated, especially when they are suddenly started or stopped, a much more intense local magnetic field for a moment makes its appearance and rapidly spreads out as a wave of radiation, by reaction with the superposed electric field, just as Larmor and others have calculated, and of course in accordance with Poynting's theorem.

The whole treatment here, with simple geometrical conceptions, is exceptionally interesting; and the resulting view of the nature of light—that it consists, as it were, of pulses running along the fibres as along stretched strings, with constant speed because their tension is proportional to their mass per unit length—is especially noteworthy, and is quite in accordance with a guess which the genius of Faraday enabled him to throw out in his famous "Thoughts on Ray Vibrations," where he says:—

"The view which I am so bold as to put forward considers therefore radiations as a high species of vibration in the lines of force which are known to connect particles and also masses together."

It is clear that if this vibrating string method of regarding waves of light be substantiated, a wave front cannot be a continuous surface, but must be, as it were, a series of isolated specks of disturbance; so also must a Röntgen pulse, and hence J. J. Thomson is able to reconcile with theory the actually experienced small ionising power of such waves, as compared with what might be expected if they really and necessarily encountered every atom in the field. They would, on the fibrous view, be in some respects more akin to a stream of kathode rays penetrating between the actual corpuscular particles of matter, and only encountering them occasionally, just as a comet or meteoric stone only occasionally encounters a planet.

One of the interesting features of the book—though it is also contained in another volume by the same author, "The Conduction of Electricity by Gases"—is the summary of a re-calculation of the results of Kaufmann's excellent experiments on the magnetic deflection of flying particles moving with very high velocity, such as can be shot off from radium. It is well known that Kaufmann proved that the mass of such charged bodies increases measurably as the speed approaches that of light; and by comparison of his results with theory he deduced, by aid of a fairly plausible assumption, that the electrical portion of the mass was about a quarter of the whole.

His assumption, however, had been that the charged particles behave like conducting spheres, so that the lines of force would at high speeds re-distribute themselves on their surface in accordance with the calculations of G. F. C. Searle for metal spheres.

J. J. Thomson, however, prefers to regard electron or corpuscular particles as behaving like perfect points, only points the field of which is non-existent within a certain small sphere surrounding each, which therefore constitutes the charged surface. On this view, the distribution of the lines on the bounding surface of the flying particle would obey a different law from that of a conducting sphere at high speed, and the result of a re-calculation is to make electrical mass *equal* to the whole mass, to a remarkable degree of approximation. Thus, for instance, when the speed is $2{\cdot}85 \times 10^{10}$ centimetres per second, the observed mass is measured as 3·09 times

the mass of the same particle for slow speed; calculation makes it 3·1 times. When the speed is $2{\cdot}59 \times 10^{10}$, the observed mass ratio is 2·04; calculation makes it 2·0. When the speed is $2{\cdot}36 \times 10^{10}$, observation gives the ratio 1·65, calculation 1·5, which is not quite so good an agreement; but even this is nearer than anyone could have anticipated, while the other results are extraordinarily close. If Kaufmann's results stand the test of criticism and repetition, they constitute a verification of a fact which is of the utmost importance and of the highest theoretical interest, for it has the effect of reducing the whole Matter in the universe to Electricity, not as a speculation, but as an established truth. It would be rash to jump to such an important conclusion too hastily; and there remains a great outstanding difficulty, hardly yet even faced, concerning the nature of positive electricity—that vague and cometary termination of lines which at the other end are intensely concentrated.

Moreover, the view taken by J. J. Thomson of the nature of the lines of force—whereby their momentum when moving depends upon the mass of ether vortically included in each and inseparable from it—cannot be said exactly to *explain* "mass." Material mass is first explained electrically, and then electrical mass is relegated to the inertia of ether,—not the great bulk of ether, which may be as regards locomotion immovable, but the core of the columnar vortices associated with and essentially constituting the particles of which atoms of matter are composed. The massiveness of ether itself would thus be an unexplained fundamental fact, and its density would have to be regarded as extremely great. The probably high density of ether had already been surmised by FitzGerald and others, and although by this means the cosmos is reduced to a kind of glorified hydrodynamics, yet the fundamental properties of the continuous fluid itself remain unexplained and to all appearance inexplicable.

This may be regarded as a defect, but, after all, explanation always proceeds by stages, reducing the complex to the simple and introducing unification; it can hardly be considered likely that any theory accessible to us here and now can give anything approaching an *ultimate* explanation even of the simplest thing. If the present theory can be substantiated, with whatever modifications and enlargements may be found to be necessary, it will be an immense step in advance; but it would be premature to suppose that these views are in any sense final, or that they will be promptly and universally accepted. They have been led up to by the progress of science during the last quarter century, and a welcome has been gradually prepared for some of them, but the discrete and real physical nature of the lines of force radiating from an electric charge seems to me a novelty; although, as said before, a fibrous vortex structure for the ether had already been suggested and shown to be competent to transmit transverse vibrations. This essential requirement for any ether, the transmission of transverse vibration, necessarily involves some "structure" in the ether, as Lord Kelvin and others have all along perceived. Lord Kelvin favoured at one time a laminar structure, FitzGerald a fibrous structure, and Hicks had his own conception of a vortex sponge. But the difficulty in most cases was to show that these arrangements were stable and could persist without mutual destruction or hopeless wire-drawing. It is not clear whether this difficulty has or has not yet been attacked by J. J. Thomson in connection with the pictorial representation which he now brings forward.

He shows clearly, somewhat on the same lines as Mr. Heaviside, how sudden jerks or accelerations given to the lines must result in radiation, and he makes many interesting thumb-nail calculations in connection with their behaviour, among other things showing that the mass of bound or associated ether in an electrostatic line is such that if moving with the speed of light it would exactly equal the electrostatic energy of the field per unit volume; though how an electric field is to be thus thought of in any *static* manner is not clear to me. Also he is able to regard the re-distribution of the lines of a charge in rapid motion (first calculated by Mr. Heaviside in the *Phil. Mag.*, April, 1889) as not only analogous to, but as really corresponding to, the tendency of a moving cylinder to set itself broadways to the direction of motion. Furthermore, the lines of force behave very exactly as stretched elastic threads; for though their section is not uniform, their tension, *i.e.* their total stretching force, varies everywhere with their mass per unit length, so that the rate of propagation of waves along them is constant.

Altogether a fascinating and most readable book for students of physics and chemistry.

OLIVER LODGE.

SIR A. GEIKIE'S RECOLLECTIONS.

Scottish Reminiscences. By Sir Archibald Geikie. Pp. xii+447. (Glasgow: Maclehose and Sons, 1904.) Price 6s. net.

SCIENTIFIC readers will perhaps turn with most interest to the chapter in this charming book in which Sir Archibald, the last Scotchman for the time being who has directed the work of the Geological Survey of Great Britain, tells the story of the Scottish School of Geology. It is interesting to read along with it the pathetic lament of Principal Forbes, in Edinburgh, in 1862.

"It is a fact which admits of no doubt that the Scottish Geological School which once made Edinburgh famous, especially when the Vulcanist and Neptunian war raged simultaneously in the hall of this society"—the Royal Society of Edinburgh—"and in the class rooms of the University, may almost be said to have been transported bodily to Burlington House. Roderick Murchison, Charles Lyell, Leonard Horner, are Scottish names, and the bearers of them are Scottish in everything save residence—our younger men are drafted off as soon as their acquirements become known. Of all the changes which have befallen Scottish science during the last half century, that which I most deeply deplore, and at the same time wonder at, is the progressive decay of our once illustrious Geological School. Centralisation may account for it in part but not entirely."

But the nation, which did not greatly mourn when it sent its sixth King James to the sister country, did not, I think, suffer any more acutely when it saw its eminent sons, Sir Roderick Murchison, Sir Andrew Ramsay, and Sir Archibald Geikie, filling in uninterrupted succession the position of Director General of the Geological Survey of Great Britain. England may congratulate herself that she showed no narrow provincial jealousy, but chose the best men she could find in the island, to direct its geological survey, and their work and their fame are hardly less dear to their countrymen, because their later years were spent, as perhaps their best known work may have been done in the south. They owed their whole training and equipment to the Scottish School of Geology.

But the note of lamentation was a little too high pitched even for the days when Forbes struck it. It is true that the disputes of the Vulcanists and the Neptunists were rather forgotten with the names of Hutton and of Jamieson. In Forbes's time it had come to be recognised that both schools were substantially in the right—that volcanic forces on the one hand and water and ice on the other are forces almost equally potent in fashioning the earth as men knew it then and as they know it now, and Murchison, Lyell, Ramsay, Geikie brought people to recognise that each of the great elements took its own dominating part in sculpturing our hills and valleys, and in laying down and dislocating the strata of our rocks. In Scotland itself there were plenty of geologists to whose memories Sir Archibald Geikie pays loving and grateful tribute, who had never left their native Scotland. Two Edinburgh journalists, Charles Maclaren, who founded "The Scotsman," and Hugh Miller, who was "The Witness," spent a great part of their lives in the field of geology. Robert Chambers worked as hard on geological subjects as he did on the improvement of the literature and of the lives of his countrymen, and Principal Forbes himself, Mr. Peach, and Prof. James Geikie have not allowed the indigenous Scotchman to lose his claim to a great place among contemporary geologists.

Sir Archibald Geikie shows that his hand has lost none of its cunning, in the delightful word pictures he has given us of some of these famous and only half forgotten men of the early Victorian era. Here is a charming cameo:—

"The illustrious Principal Forbes himself was widely known to the geological world for his researches on the glaciers of the Alps and of Norway, and on earth temperature. As one saw him in the street or in the class room, he looked singularly fragile, and it was not easy to realise how such a seemingly frail body could have undergone the physical exertion required for his notable Alpine ascents. His tall, spare figure might be seen striding from the University to the rooms of the Royal Society, of which for many years he was the active secretary. His clear brown eyes wore a wistful expression and his pale face and sunken cheeks showed how his well-chiselled features had been preyed on by serious illness. Round his long neck he always wore one of the large neckcloths then in vogue, and above this, when out of doors, he carried a thick muffler, from under which as one passed him, one might hear now and then the cough that told of the malady from which he was suffering. In his own house, especially when showing some of the beautifully artistic water-colour drawings which he had made in the course of his wanderings, the then white, almost transparent, hands told the same tale of suffering."

Take another cameo, equally striking, of that wonderful stonemason and editor, Hugh Miller:—

"His appearance in the streets was certainly most uneditorial. Above the middle height, strongly built with broad shoulders, a shock of sandy hair, large bushy whiskers, and dressed in rough tweeds, with a shepherd's plaid across his shoulder, he might have been taken for one of the hill farmers, who on market days come to Edinburgh from the uplands of the Lothians He had the true 'Highland man's ling,' the elastic, springy and swift step of the mountaineer, accustomed to traverse shaking bog and rough moor. As he swung down the North Bridge, wielding a stout walking stick, looking straight before him, his eyes apparently fixed on vacancy, and his lips compressed, one could hardly help turning to look after him and to wonder what manner of man he could be."

Of the innumerable excellent stories which delight the readers of Sir Archibald's reminiscences I shall quote only two, and they shall be in connection with well-known scientific names. One tells us how "the late Professor Tait, so widely known, and so affectionately remembered, used to cite one of the answers he received in a class examination. The question asked was 'Define transparency, translucency, and opacity,' and the following was the answer, 'I am sorry that I cannot give the precise definition of these terms. But I think I understand their meaning, and I will illustrate it by an example. The windows of this class room were originally transparent, they are at present translucent, but if not soon cleaned they will become opaque.'"

Many old Edinburgh students will still "affectionately remember" these occasionally translucent windows, and will know how their never-to-be-forgotten professor would welcome the answer.

The only other quotation I shall permit myself is from a letter written by Ami Boué, a delightful old geological friend of Sir Archibald Geikie's younger days, who had been educated in Edinburgh, where he was caught up in his youth—about the time of Waterloo—in the maëlstrom of the great geological duello between the Vulcanists and the Neptunists. Boué wrote an "Esquisse Geologique sur l'Ecosse." which Sir Archibald describes as "a most valuable treatise, in many respects far in advance of his time." Born in Geneva, with German and Austrian connections, and educated in Scotland, he seems to have spoken most of the tongues of Europe with equal courage and inaccuracy. His Edinburgh days, however, were in 1870 far in the background of his life, but there are few Englishmen or Scotchmen who would have ventured to describe their feelings in a tongue with which they had been familiar in early life, as Ami Boué did, during the calamitous Franco-German war.

"The dreadful war pre-occupations did take me all time for thinking at scientific matter, and now perhaps that distress will approach till nearer our

abode! When you will know that I have very good and near parents in both armies, and you perceive the possibility of parents killing themselves without recognising themselves, nor having the opportunity to do so, you will understand that I have often headach when I ride the newspapers or hear from the quite useless slaughters which have been provocated only by those men at the head of the human society."

Too much language must have made his charming old geological friend a little mad, for Sir Archibald tells us that "all the letters to me, extending over a period of thirteen years," of this too cosmopolitan man of science, "were written in broken English," of which the letter above is a specimen.

The book is full of passages which recall one of the most delightful, and one of the earliest of Sir Archibald's books on the scenery of Scotland. I take a grateful farewell of the "Reminiscences" if you will allow me one more extract in illustration :—

"The fate of the Celt in the Highlands has been far different. There he has found himself in a region of mountains too rugged and lofty for cultivation, save along their bases, and too continuous to permit easy access from one district to another. . . . Shut in among long, narrow, and deep glens, he has cultivated their strips of alluvium, but has too often found the thin stony soil to yield but a poor return for his labour. For many a long century he had to defend his flocks and herds from the wolf, the fox and the wild cat. The gloom of his valleys is deepened by the canopy of cloud which for so large a portion of the year rests upon the mountain ridges and cuts off the light and heat of the sun. Hence his harvests are often thrown into the late autumn, and in many a season his thin and scanty crops rot on the ground, leaving him face to face with starvation and an inclement winter. Under these adverse conditions he could hardly fail to become more or less subdued and grim."

In passages like this, admirable in description and rich in human sympathy, the book abounds.

W. J.

THE NEW ZEALAND FAUNA.

Index Faunae Novae Zealandiae. Edited by F. W. Hutton. Pp. viii+372. (London: Dulau and Co., 1904.) Price 10s. 6d. net.

WITH the exception of the valuable introduction, by the editor, which appeals to a somewhat wider circle, this is essentially a book of reference, and as such is all-important to the scientific worker. In drawing up the list of the fauna, Captain Hutton has had the assistance of specialists in various branches of zoology who have undertaken the groups with which they are most familiar, so that the work may be regarded as thoroughly complete and up-to-date. Only two land mammals—bats are recognised as indigenous to the islands, the so-called Maori rat (*Mus exulans*) having apparently been introduced from Polynesia. This species, together with other wild forms introduced by human agency, are noticed in an appendix, and the reader will probably be surprised to find how large a list of foreigners has thus been added to the indigenous fauna. It should be mentioned that the text of the work is an "index" pure and simple, not even the local distribution of the various species being given.

After a brief historical survey of the acquisition of our present knowledge of the New Zealand fauna, Captain Hutton enters on a detailed discussion of the origin and relationships of that fauna, and since this is a subject to which he has for many years devoted special attention, his matured conclusions are of the highest value and importance.

The migratory portion of the fauna is very small, including only some half-dozen species of birds. The preponderating stationary portion may, according to Captain Hutton, be divided into a small aboriginal element, comprising species with no near relatives elsewhere, and larger Malay, Australian, and Antarctic elements, as well as several smaller ones. Among the aboriginal forms, that is to say, those which appear to have been inhabitants of the islands for a very long period, the author includes the short-tailed bat (Mystacops), the tuatera, and the kiwi. Taking a broad view of the fauna, it may be said that the terrestrial portion is mainly of Malay origin, but with somewhat strong Holarctic and Neogæic connections. This opinion is important in connection with the view that has been elsewhere expressed as to the Asiatic origin of the Australasian marsupials.

From the occurrence of a number of animals which it is impossible to believe could have crossed the sea, the author is of opinion that New Zealand is not entitled to be regarded as an oceanic island, but that at an epoch relatively remote it formed part of a large continent.

The land shells of the genus Endodonta, which range all through Polynesia, New Zealand, eastern Australia, New Guinea, and the Philippines, with an outlier in Ceylon, afford the best evidence in favour of a Polynesian continent, the Cingalese outlier pointing to the conclusion that this group of molluscs originally came from the north. The molluscan evidence will not, however, explain the South American connection.

The best zoological evidence of the latter connection, by way of Antarctica, is afforded by the earthworms of the family Acanthodrilidæ, which are unknown north of the equator, although their occurrence in Madagascar may point to a northern origin. The primary northern origin of the mainly fresh-water fishes of the genus Galaxias may perhaps also be indicated by the existence of the allied Cromeria in the Nile. Additional evidence of a connection with Patagonia is afforded by the occurrence in the Tertiary strata of South America and New Zealand of quite a number of shallow-water marine invertebrates, as, indeed, has been recently pointed out by Dr. von Ihering. Further, the occurrence of these forms in older strata in South America than in New Zealand points to the conclusion that the migration took place from the former to the latter area.

Lack of space alone prevents us from discussing in greater detail Captain Hutton's very interesting and suggestive views.

R. L.

OUR BOOK SHELF.

A History of the Daubeny Laboratory, Magdalen College, Oxford. By R. W. Günther, M.A., F.L.S. Pp. vi+137; 3 full page plates. (London: Henry Frowde, 1904.) Price 5*s.* net.

OXFORD chemistry is entering on a new phase of its existence. Up to the present time the theoretical teaching has been excellent, but partly owing to lack of accommodation and partly through other causes, the practical teaching has not reached so high a standard. Mr. Günther's book is a sort of commemoration of the opening of the reconstructed chemical laboratory at Magdalen College. The laboratory, apart from the Physic Garden, which is nearly four hundred years old, was founded in 1842, and it was the scene of Daubeny's labours both as chemist and botanist. His chemistry lectures were, however, given in a basement of the old Ashmolean building. It is to a certain extent typical of the earlier days of Oxford science that most of the work was relegated to cellars. Brodie's "last word on the formula of ozone" was said in a cellar at Balliol, and in the same cellar much of Dixon's excellent work on the rates of explosion in gases was done. Harcourt's classical experiments on velocity of chemical change were performed in a basement at Christ Church. Things are changing now. New laboratories have been built both at Christ Church and Magdalen, and in both, research laboratories, with the best appliances, give hope that chemical research in Oxford many be entering on a new lease of life.

Mr. Günther gives a very minute and interesting account of the laboratory now under his charge. Not the least interesting is his description of the collection of old apparatus which has been lying, fortunately unbroken, for many years in the laboratory. A complete meteorological record from 1869 has been kept, and the monthly averages are given in an appendix. A list of Daubeny's researches is also appended; the number of papers is very large, considering the fact that he was the holder of three several professorships—chemistry, botany, and rural economy. The researches of later workers in the laboratory are described in full. Mr. Günther has evidently been misled by the politeness of one of the learned societies. It is scarcely considered a mark of distinction for an author to have his paper "deposited in full in the Society's Archives."

The registers of attendance at the lectures of Daubeny are printed in full from 1826, with notes of the after careers of the students. It is a curious fact that fully three-quarters of the early attendants of science lectures in Oxford afterwards took Orders, and among them we find three archbishops, Tait, Whately and Thomson. In these later days science is apparently not so necessary for the education of the clergy.

Abriss der Biologie der Tiere. By Prof. H. Simroth. 2 vols. Pp. 157 each. (Leipzig: Göschen.)

THESE little books correspond to the series issued in this country by Messrs. Newnes, as the "Story of Fish-Life" and the like. But Dr. Simroth, possessing as he does a great knowledge of animal bionomics, has condensed within two small volumes all the essential facts of comparative physiology of animals in a way that is paralleled by no English work except Semper's "Animal Life." Unfortunately the Germans, with few exceptions, do not arrange and select their elementary science in a way that assists the beginner. Almost on the first page we meet with "idioplasma" and "chromosomes," a fact which is eloquent of the distance between writer and learner. Whilst this work is one of great value to teachers, it is well to understand that it is useless to those beginning the subject. The reviewer, however, as one who has known the stimulating character of Prof. Simroth's teaching, gladly acknowledges the suggestive and clear way in which the influence of gravity, light, heat, and other radiations are referred to. These, and the concluding chapters on reproduction, rudimentary organs, and habitat, are well worth the attention of those who have already acquired a practical knowledge of biology.

From India to Fergana. Description of a Journey made in 1898 by Lieut.-Colonel V. T. Novitskiy, being part of vol. xxxviii. of the *Memoirs* of the Russian Geographical Society. Pp. 297; with a map and 18 photographs. (St. Petersburg, 1903.)

STARTING from Srinagar, the author went first to Leh; thence, proceeding in a northern direction, he crossed the Karakoram Plateau, reaching the Karakash River, or Khotan-daria, at the Chinese post Shahi-dula. Then, instead of taking one of the usual passes across the Raskem Range, the Russian traveller went through a more western, formerly unknown pass, Karlik-davan, which proved to be extremely difficult, especially in the gorge of the Tagra-su. Descending next to the valley of the Ulyuch-su, the party soon reached Kargalyk, in Kashgaria, and Yarkand, and went to Russian Turkestan, following one of the usual routes. The author gives very good descriptions of Kashmir and of the dreary Karakoram Plateau, about 15,000 feet high in its high valleys, which are covered with alluvial deposits from old desiccated lakes, and are surrounded with bare mountains reaching an altitude of 24,600 feet in the Ak-tash group of peaks. He describes further the Alpine zone, intersected with wild gorges, which is usually known on the maps as the Raskem Range, but represents in reality an intermediate zone between the plateau and the plains of Kashgaria. He gives detailed lists of the plants he collected and of the birds he saw, and also most striking photographs, artistically reproduced. A map of the Pamirs and the surrounding regions, 27 miles to the inch, and a very interesting cross-section, based on the author's barometric measurements, are added to this valuable work.

Dissertations on Leading Philosophical Topics. By Alexander Bain. Pp. vi+277. (London: Longmans, Green and Co., 1903.) Price 7*s.* 6*d.* net.

THIS volume consists of fifteen essays on logical, psychological and ethical topics that have been previously published in the pages of *Mind* or elsewhere. Nevertheless a special interest attaches to it because the essays represent the maturest conclusions of the late Prof. Bain upon subjects to which he had devoted his attention with so conspicuous success throughout his long and distinguished career, and were designed by him to supplement the two great works on psychology which ill-health prevented him from again reissuing. The essays exhibit all that wide learning, that clearness and vigour of intellect, and that width of sympathy and interest which gave Bain's works on psychology a place in the foremost rank and secured for him a world-wide reputation. Very characteristic are the two essays in which he insists on the importance for psychology of physiological considerations and psycho-physical experiment, and at the same time defines their scope and their true relations to the introspective method. The volume concludes with an essay on the examination-system that assumes ever vaster proportions in this country in spite of many denunciations. Here Bain, recognising the necessity of examinations, appears as an advocate of improvement in the art of examining and of restriction rather than abolition of the system.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Relation between Uranium and Radium in some Minerals.

IN the course of an investigation which I am conducting on uranium-bearing minerals, the detailed results of which will be published shortly, I have come upon a point which seems to be of sufficient interest to warrant immediate publication. This is the close agreement between the amount of uranium and the amount of radium present in those minerals which have been examined.

The method which has been employed is briefly as follows:—A weighed quantity of the powdered mineral is introduced into a small glass bulb, which is connected with a larger bulb by a short tube. Attached to the bulb containing the mineral is another small bulb containing a small quantity of a suitable acid. The whole apparatus is sealed up at a slightly diminished pressure, and by tilting, the acid is brought into the bulb with the mineral, and the complete decomposition of the latter effected by gentle heating. At the end of a couple of days the larger bulb is sealed off from the smaller and allowed to stand for two hours to permit any rapidly decaying emanation which it may contain to dissipate. A small quantity of strong sodium hydroxide solution is introduced into the bulb, and the walls are thoroughly wetted in order to remove the acid fumes. The air contained in the bulb is then transferred to an air-tight electroscope and the rate of leak measured. In comparing the results obtained with different minerals the rate of leak at the end of three hours has been chosen, since at this time the rate of decay of the excited activity and its rate of formation are in equilibrium, and the readings of the electroscope are constant over considerable periods. The quantity of uranium in the solution is determined by analysis, and the ratio between the volumes of the two parts of the apparatus determined by measuring their separate capacities.

The results which have been obtained are as follows:—

No.	Substance	Per cent. Uranium	Grams Uranium taken	Leak divisions per min.	Ratio leak to Uranium
1	Uraninite	82·5	0·1067	22·5	211
2	Gummite	66·1	0·0982	20·8	212
3	Uranophane	46·6	0·0671	12·1	181
4	Uraninite	83·9	0·0994	20·6	207·2
5	Samarskite	9·5	0·0292	6·4	218

Nos. 1, 2, 3 and 5 from North Carolina; No. 4 from Branchville, Conn.

The slightly low value of the constant in No. 3 can be explained by the fact that this mineral at ordinary temperature gives off constantly a small proportion of its emanation, and is therefore not in complete equilibrium.

These results show a direct variation from those obtained by Mr. Strutt (*Proc.* Roy. Soc., lxxiii., 191), which may perhaps be explained by the fact that he secured the emanation by heating his minerals. Experiments which I have made show that on heating samarskite to low redness only 10 per cent. of the total emanation is given off, and that heating to bright redness releases only 20 per cent. of the total emanation obtained when the very finely powdered mineral is completely decomposed by heating with concentrated sulphuric acid. BERTRAM B. BOLTWOOD.

139 Orange Street, New Haven, Conn., U.S.A., May 7.

The Source of Radium.

As the subject of the origin of radium is being discussed, I may perhaps be permitted to make a suggestion.

The source of radium is at present being looked for on the assumption that it is the disintegration product of a substance of higher atomic weight. If this is so, we have apparently to choose between uranium and thorium. Mr. Soddy's experiment throws serious doubts upon the former being the source. The products of the latter appear to have been sufficiently far traced to render it doubtful that it can be the source. Again, the element thorium seems to be scarce in, or even absent from, some radio-active pitchblendes, if the older analyses are to be relied upon.

I would suggest that radium may not be derived purely as a disintegration product, but as an atomic combination of radio-active products with some of the elements present in pitchblende. Thus radium would represent the synthesis of an element, not its decomposition. On this view some of the radio-active products of uranium (or thorium) can, in virtue of their great kinetic energy, enter into the atoms of intermixed substances, such as barium, bismuth, &c., giving rise to the new atom radium. The new atom is, however, not very stable, and is consequently short lived. Hence its radio-activity.

If this hypothesis is correct, we should seek to observe the genesis of radium not in any one of the radio-active elements, but in molecular intermixtures of these with the various bodies we know to be conspicuously present in pitchblende, seeking among the various combinations for a positive result. The quantities of radium (or its emanation) to be expected as generated in a given time remain, of course, the same as on the hypothesis of disintegration; thus the experimental investigation presents no additional difficulties beyond its greater prolixity. J. JOLY.

Trinity College, Dublin, May 17.

As Mr. Soddy is absent from England, it may be permitted to me to comment on Prof. Joly's letter. The idea had occurred to us; but, as remarked, the experiments would be very "prolix."

A more promising field of research appears to be to try to ascertain whether the immense amount of energy evolved in various forms during the disintegration of the radium emanation may not be able to cause chemical change of a constructive nature; for example, to change bromine into iodine. An attempt has been made to see if this was the case, but without a positive result. That iodine would be the product of an addition of energy to bromine is of course a mere guess; but iodine is easily tested for, and hence the experiment. The difficulty will be in recognising with certainty the product of any such change, for the quantity of matter to be produced is, of course, extremely small. It is only, however, by such "mad" experiments that the capabilities of the radio-active bodies can be ultimately gauged. WILLIAM RAMSAY.

Radio-activity of Russian Muds and Electrification of Air by Metals.

THE researches of Elster and Geitel (*Phys. Zeitschr.*, v. p. 11) having led to the detection of radio-active power in the fine mud or "Fango" of the Italian watering-place Battaglia, induced me to undertake a study of the Russian muds in this character. Out of the five kinds of muds hitherto obtained by me and studied in a desiccated state, two muds, viz. that of the Odessa Kooyalnitzky Liman and that of Arensburg, on the Isle of Oesel, have proved undoubtedly to possess radio-activity, the first being radioactive in a higher degree than the second. In these researches we proceeded in a manner quite analogous to that of Messrs. McLennan and Burton in studying the electrical conductivity of the air (*Phil. Mag.*, v. p. 699, 1903). The present experiments were carried out with the most active participation of Mr. Athanassieff.

We employed two cylinders, a brass one 8·3 cm. in diameter and 20 cm. high, and another of zinc, 22·5 cm. in diameter and 35 cm. high. In each cylinder there was fixed along the axis a brass wire which was supported by an amber cylinder placed in a brass guard tube. The latter was connected with the earth, and embedded in an insulating ring put into an opening of the upper base of the cylinder. The wire of either cylinder could at will be connected with one pair of quadrants of a Dolezalek electrometer, the other pair being connected with the earth, and the leaf was charged to 100 V by means of a battery of storage cells. The wire, also of brass, connecting the cylinder wire with the electrometer, and the point of connection of that wire

with either cylinder wire, were surrounded by brass tubes connected with the earth. The sensitiveness of the electrometer was such as to produce for a ΔV of 0·01 V, a shifting of about 7 mm. on the scale. The connection of the cylinder wires with the earth was brought about by touching them with brass wires connected with the earth. In the whole there was not on the path from the cylinder wire to the electrometer any contact of two different metals. The cylinder was charged, as a rule, to 100 V by a battery of storage cells.

During the progress of these experiments a very interesting phenomenon presented itself. It was found that when either of the cylinders is connected with the earth, the wire enclosed within it, after being disconnected from the earth, immediately begins to get electrified, *i.e.* the electrometer thereupon indicates a rise of a potential, which continually increases during a certain interval of time, some hours in the main, before reaching a limiting value. (The electrification was observed when the mud was removed from the cylinders.) The wire contained in the zinc cylinder becomes positively electrified, whilst that in the brass cylinder becomes negatively electrified. Having remarked such a phenomenon, we introduced into the brass cylinder which opened from beneath, a zinc cylinder, placed coaxially so as to enclose the wire. This cylinder was in metallic connection with the surrounding brass one. In this case, too, the wire acquired a potential, but it was opposite in sign to that it acquired without such a zinc cylinder being merely enclosed in the brass cylinder, *i.e.* it became positively electrified. The maximum value of the potential produced in the wire amounted in our observations to 0·2 V. This maximum value depends, it seems, upon the degree of ionisation of the air in the cylinder.

We also replaced the zinc cylinder at the interior of the great brass cylinder by others of lead, aluminium, iron and silver, with the effect that the two former acted in the same direction as the zinc cylinder; the lead cylinder, which, by the bye, proved very radio-active, gave the strongest effect (about 0·35 V), whilst aluminium took the last place, zinc remaining in the middle. The iron and the silver cylinders, on the contrary, exerted the same action as the main brass cylinder, giving a negative electrification, but to a less degree.

The phenomenon we have observed seems to be in correspondence with effects produced in metals by air ionised with Röntgen rays (f. Borgmann and A. Gerchun, *C. R.*, cxxii. p. 378, 1896; Minchin, the *Electrician*, March 27, 1896; Rutherford, *Phil. Mag.*, xliii. p. 241, 1897). It may perhaps give the explanation of atmospheric electricity; and it is also of interest in the fact that here we take electrical energy directly from the air. I. BORGMANN.

Physical Institute, The University, St. Petersburg, May 9.

Graphic Methods in an Educational Course on Mechanics.

It is difficult to reconcile Mr. Milne's opening statement (NATURE, May 5, p. 5) with the rest of his letter. He begins by venturing to think that no one will gainsay Mr. W. Larden's main contention (NATURE, April 28, p. 607) that "analytical methods give a grasp of the principles of statics while graphical methods disguise them," and he goes on to give half a dozen instances confuting it. Mr. Larden wrote to elicit opinions from those who have taught mechanics, and as I have had only one pupil, a very troublesome one, namely, myself, I cannot think that my opinions are invited. But when Mr. Milne thinks that no one will gainsay the contention, the challenge is a wide one, and I deny it emphatically, and know that there are hundreds of men who will agree with me. These men are not teachers or mathematicians, but those who have to use mathematics for their profession or trade.

I have the highest admiration for all those to whom science is an end in itself. I fully appreciate the attitude of mind (the butt of so many jokes) which feels that mathematics and other sciences become degraded by useful applications. But for one true mathematician there are a thousand men to whom mathematics are but a means to an end. Many of these, like myself, are not mathematically minded (as Mr. Larden probably counts mathematics), and with the exception of Maxwell's "reciprocal figures" and a few others, we have had to work out graphical methods mainly for ourselves. Teachers are now coming round, or as Mr. Larden would put it, giving way, or as I would put it, waking up, and are recognising that analytical language, powerful as it is for research, is not paramount for explanation. "I believe," wrote Prof. J. Perry in his "Spinning Tops," "that there are very few mathematical explanations of phenomena which may not be given in quite ordinary language to people who have an ordinary amount of experience. In most cases the symbolical algebraic expression must be given first by somebody, and then comes the time for its translation into ordinary language."

I agree with the whole of Mr. Milne's letter except the first few words, and, like him, "I believe the best results will be obtained when the two methods are used side by side." Of my own acquaintances, about one in five prefer analytical methods, but the others have a diagram in their heads, if not before them on paper as a guide to bring it vividly before the mind (to borrow Mr. Larden's words). Mr. Larden concludes, "graphical work consumes an amount of time that seems out of proportion to the mental training and knowledge of principles gained." The title of his letter shows that he has "an educational course" in view, and *qua* education, "mental training and knowledge of principles" is the true and only object. His pupils should emerge as mathematicians. But those who have to use statics professionally would not hesitate to consume twice or thrice the time on a graphical method if it carries conviction of truth with it, as it does to two or three at least out of five of my acquaintances.

Mr. Larden dates his letter from Devonport, and this suggests that some of his pupils hope to become naval officers and not wranglers; that mathematics will be used by them in after life as a means to an end. Would he deny the use of a piece of string on a globe to explain "great circle sailing," or does he use a formula applicable generally to figures of revolution, of which the earth and Saturn's ring are particular cases? Sumner's method may be disguised in algebra, but it must be confessed that the famous "line" as discovered by him was a bit of pure graphics.

It may be impossible for Mr. Larden to appreciate the geometrical point of view, for my contentions are exactly the opposite of his first and fourth. For us non-mathematicians, "graphical methods give a grasp of the principles of statics, while analytical methods disguise them," and "analytical methods confuse learners of statics." The second contention, "Analytical methods must be mastered in any case," needs the addition of the words "by the help of diagrams." If there be any truth in the third contention, that "analytical methods connect statics with dynamics," it is of small importance if they fail to elucidate dynamics. Nature herself gainsays these contentions with the parabola of the fountain, the ripple of the pond, and the slope of the sand hill.

A. P. TROTTER.

8 Richmond Terrace, Whitehall, S.W., May 13.

ANY educational course in mechanics should undoubtedly be based first of all on experiment. If such is the case, it is practically impossible for any student using "graphical methods" to make the wild "shots" referred to by Mr. Larden (vol. lxix. p. 607), who seems to have been very unfortunate in the kind of boy he has received from "a preparatory school"; or is it the boy who has been unfortunate in his previous training? Has Mr. Larden considered the possibility of the "method of teaching" adopted being wrong in the aforesaid school? Surely there is no inherent quality in "graphical methods" to cause these wildest of "shots." The writer's experience goes entirely against this idea, and supports the contentions set forth by Mr. Milne.

Mr. Larden writes:—"If then, there be not time for both, it is the latter (Graphics) that should be sacrificed." If time is so short that some sacrifice must be made, the

writer is of opinion that it would be better to take a less comprehensive course than to omit "graphical methods" entirely.

The best method for mechanics, as for all physical sciences, is:—

(1) Experimental work to be carried out by the boys.

(2) Consideration of, discussion on, and deduction from the experimental data obtained by the boys, with an occasional demonstration by the teacher to clench any particular point. This treatment of the experimental work to involve both analytical and *graphical* methods.

In fact, a truly educational course in mechanics is impossible without experimental work. Granted this experimental work, the writer is of opinion that the aim of the students will be considerably improved, and not only so, but there will be a complete absence of wild "shots."

S. IRWIN CROOKES.

Secondary and Technical School Clay Cross, Chesterfield, May 15.

EUGENICS; ITS DEFINITION, SCOPE AND AIMS.[1]

EUGENICS is the science which deals with all influences that improve and develop the inborn qualities of a race. But what is meant by improvement? We must leave morals as far as possible out of the discussion on account of the almost hopeless difficulties they raise as to whether a character as a whole is good or bad. The essentials of eugenics may, however, be easily defined. All would agree that it was better to be healthy than sick, vigorous than weak, well fitted than ill fitted for their part in life. In short, that it was better to be good rather than bad specimens of their kind, whatever that kind might be. There are a vast number of conflicting ideals, of alternative characters, of incompatible civilisations, which are wanted to give fulness and interest to life. The aim of eugenics is to represent each class or sect by its best specimens, causing them to contribute *more* than their proportion to the next generation; that done, to leave them to work out their common civilisation in their own way.

The course of procedure that lies within the functions of a learned and active society would be somewhat as follows:—

(1) Dissemination of a knowledge of the laws of heredity so far as they are surely known, and promotion of their further study. Few seem to be aware how greatly the knowledge of what may be termed the *actuarial* side of heredity has advanced in recent years. The *average* closeness of kinship in each degree now admits of exact definition and of being treated mathematically, like birth- and death-rates, and the other topics with which actuaries are concerned.

(2) Historical inquiry into the rates with which the various classes of society (classified according to civic usefulness) have contributed to the population at various times, in ancient and modern nations. There is strong reason for believing that national rise and decline are closely connected with this influence.

(3) Systematic collection of facts showing the circumstances in which large and thriving families have most frequently originated; in other words, the *conditions* of eugenics, on which much more information is wanted than is now to be had. It would be no great burden to a society, including many members who had eugenics at heart, to initiate and to preserve a large collection of such records for the use of statistical students. The committee charged with the task would have to consider very carefully the form of their circular and the persons entrusted to distribute it. They should ask only for as much useful information as could be easily, and would be readily, supplied by any member of the family appealed to. The point to be ascertained is the *status* of the two parents at the time of their marriage, whence its more or less eugenic character might have been predicted if the larger knowledge that we hope to obtain had then existed. The reasons would have to be shown why the children deserved to be entitled a "thriving" family. A manuscript collection such as this might hereafter develop into a "golden book" of thriving families. The act of systematically collecting records of thriving families would have the further advantage of familiarising the public with the fact that eugenics had at length become a subject of serious scientific study by an energetic society.

(4) Influences affecting marriage. The remarks of Lord Bacon in his essay on death may appropriately be quoted here. He says, with the view of minimising its terrors:—

"There is no passion in the mind of men so weak, but it mates and masters the fear of death. . . . Revenge triumphs over death; love slights it; honour aspireth to it; grief flyeth to it; fear pre-occupateth it."

Exactly the same kind of considerations apply to marriage. The passion of love seems so overpowering that it may be thought folly to try to direct its course. But plain facts do not confirm this view. Social influences of all kinds have immense power in the end, and they are very various. If unsuitable marriages from the eugenic point of view were banned socially, or even regarded with the unreasonable disfavour which some attach to cousin-marriages, very few would be made. The multitude of marriage restrictions that have proved prohibitive among uncivilised people would require a volume to describe.

(5) Persistence in setting forth the national importance of eugenics.

There are three stages to be passed through before eugenics can be widely practised. First, it must be made familiar as an academic question, until its exact importance has been understood and accepted as a fact. Secondly, it must be recognised as a subject the practical development of which is in near prospect, and requires serious consideration. Thirdly, it must be introduced into the national conscience, like a new religion. It has, indeed, strong claims to become an orthodox religious tenet of the future, for eugenics cooperate with the workings of nature by securing that humanity shall be represented by the fittest races. What nature does blindly, slowly and ruthlessly, man may do providently, quickly and kindly. As it lies within his power, so it becomes his duty to work in that direction, just as it is his duty to be charitable to those in misfortune. The improvement of our stock seems one of the highest objects that can be reasonably attempted. We are ignorant of the ultimate destinies of humanity, but feel perfectly sure that it is as noble a work to raise its level as it would be disgraceful to abase it. I see no impossibility in eugenics becoming a religious dogma among mankind, but its details must first be worked out sedulously in the study. Over-zeal leading to hasty action would do harm by holding out expectations of a near golden age which would certainly be falsified and cause the science to be discredited. The first and main point is to secure the general intellectual acceptance of eugenics as a hopeful and most important study. Then let its principles work into the heart of the nation, which will gradually give practical effect to them in ways that we may not wholly foresee.

[1] Abridged from a note read before the Sociological Society on May 16 by Dr. Francis Galton, F.R.S.

SOME GERMAN PUBLIC LABORATORIES.

In considering the success of German manufactures we are doubtless justified in regarding education as the ultimate cause. But proximate causes are also worth noting, and among these is the facility of access to the fountain-head of science enjoyed by German manufacturers. In England, as elsewhere, a manufacturer hesitates to take scientific experts into his employ unless his industry be on rather a large scale, but in Germany, at any rate, he has for some time been able to acquire the very best of scientific aid, as it were, retail. This fact is brought home by a study of some of the German industrial testing stations recently published by M. A. Granger in the *Bulletin de la Société d'Encouragement.*

The first of these institutions on M. Granger's list is also the most interesting, since it is not a State creation, but rests, in essence, on the historically English basis of cooperation. The laboratory of the Tonindustrie Zeitung in Berlin, together with the journal from which it takes its name, thrives upon the support of nine associations of manufacturers turning out pottery, cement, builders' materials, &c. It is housed in an admirably planned building of three stories, of which the uppermost is set apart for the business of the Zeitung. The laboratories are designed for the study of such goods as bricks and tiles, terra-cotta, fireclay, earthenware, porcelain, and cement, and their primaries. The clays serving as raw materials are subjected to elutriation, to determinations of plasticity, porosity, and fusibility, and to chemical analysis. In another department they are experimentally baked; here also Seger's cones are made and furnace gases analysed. The testing of cements includes rate of hardening, variation of volume, resistance to hammering, and tensile strength. Manufactured articles, finally, undergo tests for mechanical strength and for resistance to abrasion.

The laboratory is entirely at the service of manufacturers not only for tests, but also for investigations, including geological prospecting. To round off its completeness, it carries on a patent agency and an instrument business. Altogether some fifty persons are employed.

Better known to the world at large is the Kgl. Mechanisch-Technische Versuchs-Anstalt of Charlottenburg, now removing to the remoter suburb of Gross-Lichterfelde. Founded by ordinances of the Prussian Government in 1880 and 1882, it performs investigations and tests for the various Government departments (including railways) and for private clients. There are four departments, with a supreme director. The metals department is equipped for all the usual engineers' tests and for photographic metallography; its chief glories are a 500 ton horizontal testing machine by Hoppe, and a machine for crushing tests, of which the monkey weighs 600 kg. and falls through 10 metres. The other departments are concerned with builders' materials, papers and textiles, and lubricants respectively. The paper testing of the Versuchs-Anstalt is, perhaps, the best of its kind; its methods have been rendered familiar by the book of Dr. Hertzberg, the head of the department.

M. Granger further mentions the Kgl. Chemisch-Technische V.-A. in central Berlin, which is also kept up by the Prussian Government. It appears to be practically a commercial analyst's laboratory on the large scale. The well known Physikalisch-Technische Reichsanstalt of Charlottenburg owes its maintenance not to Prussia, but to the Empire.

In this, as in other respects, Bavaria declines to stand by whilst Prussia makes the running. Since 1891, we learn, there have been a Material-Prüfungs-Anstalt and a Chem.-Techn. V.-A. in Nuremberg, both State institutions; though on a comparatively small scale, they are in a flourishing way, and are business-like enough to charge lower fees than their Prussian analogues.

W. A. C.

DR. G. J. ALLMAN, F.R.S.

George Johnston Allman was born in Dublin in the year 1824, the son of Dr. William Allman, who was professor of botany in the University of Dublin from 1809 until 1844. He entered Trinity College at an early age, and at the honour degree examination he obtained senior moderatorship and a gold medal in mathematics in the year 1843. He was thus a contemporary of Samuel Haughton, who was first senior moderator in Dr. Allman's year, and of Sir Thomas Moffett, with whom he was so long associated in Galway. Early in the 'fifties Dr. Allman was elected to the professorship of mathematics in Queen's College, Galway, one of the colleges affiliated to the then recently constituted Queen's University in Ireland, and at Galway he remained until the close of his long life. Soon after the foundation of the Royal University in place of the Queen's University, Dr. Allman was nominated one of the senators by the Crown—a signal testimony to the high reputation he had made among his friends and colleagues in the Queen's University. He held his professorship for nearly forty years, when he was obliged to retire in accordance with the Civil Service regulations respecting the age limit.

Dr. Allman's most remarkable mathematical works relate to the paraboloids (on some properties of the paraboloids, *Quarterly Journal of Mathematics*, 1874) and to the history of Greek mathematics. During the years 1877–87 he published a series of papers in Hermathena which formed the basis of his celebrated work, "Greek Geometry from Thales to Euclid" (Dublin University Press Series). He also wrote the articles in the ninth edition of the "Encyclopædia Britannica" on Ptolemy, Pythagoras and Thales. In 1884 he was elected a Fellow of the Royal Society.

Like his class-fellow, Dr. Haughton, Allman was much interested in natural history, especially in the collection and study of sea-shells. He was fond of chess, and though perhaps he would hardly have called himself a mountaineer, he thoroughly enjoyed a ramble in some mountainous district and had full experience of the fascination the mountains have exerted over so many men of science.

NOTES.

The delegates attending the assembly of the International Association of Academies were entertained by the Royal Society at a banquet at the Hôtel Métropole on Tuesday. Sir William Huggins, president of the society, occupied the chair. Lord Goschen, in proposing the toast of the evening, "The International Association of Academies," said that a hundred years ago the metaphysical interests seemed to predominate over the interests of physical science, but the conditions were now entirely reversed, and it seemed as if physical science were going to rule the world. Nations seemed to look to physical sciences as if on them their prosperity depended, and the nation which paid the greatest homage to physical sciences would be the nation which would win among the nations of the universe. But might he put in a plea at the same time for the moral and metaphysical and the political sciences? He was glad to think that in most of the academies there was a section of the moral and political sciences side by side with the physical

sciences, but they could not achieve the same striking results. He thought it highly desirable that side by side with physical sciences the societies which devoted themselves to moral and political sciences should be able to hold their own, and he appealed to the representatives of those academies to try to vie in energy and in determination to succeed with those who represented physical science alone. Replying to the toast, the Comte de Franqueville remarked that science belonged to no country, and was essentially the patriotism of humanity. Every scientific discovery, every conviction, every step of progress, whoever the author might be, in whatever country it took place, was spreading to every land like the beams of the sun illuminating the worlds. It was natural that all should contribute to that which should be a profit to all; to individual efforts and labours they gave a common impetus, in grouping and classifying the numerous problems which humanity had not yet solved.

Sir William Huggins, K.C.B., has been elected a foreign associate of the U.S. National Academy of Sciences; and also an honorary member of the Royal Philosophical Society of Glasgow.

The *Times* correspondent at Colombo announces that Dr. Castellani has discovered the bacillus of dysentery, and will shortly read a paper upon the subject before the Medical Association.

The *Globe* reports that Dr. Gottfried Merzbacher, who has been engaged for two years on a scientific expedition in the Thian-shan Mountains, in Central Asia, has returned to Munich with many objects of geological, palæontological, zoological and botanical interest.

A Reuter telegram from Malta states that a slight shock of earthquake was felt there at 6.13 a.m. on May 21.

A Reuter message from Copenhagen, dated May 21, states that the Danish scientific expedition to Greenland has arrived in the Danish colony of West Greenland, and reports that the Gjoea expedition, which started in August of last year, was found at Dalrymple Rock. All the members of both expeditions are well.

We learn from the *British Medical Journal* that the International Congress of Physiologists will hold its sixth meeting at Brussels this year from August 30 to September 3. All communications relative to the congress should be addressed to Dr. Slosse, Institut Solvay, Parc Leopold, Brussels, before July 1.

The annual meeting and conversazione of the Selborne Society will be held at the Civil Service Commission, Burlington Gardens, to-morrow, May 27. Lord Avebury, the president of the society, will give an address. There will also be a lecture, by Prof. B. H. Bentley, on "Flowers and their Insect Visitors," and one by Mr. Fred Enoch on "Colour Photography of Living Insects."

We have received from the secretary of the Library Association a report of the proceedings of the committee of the Library Association on binding leathers. We notice that more than sixty institutions have undertaken to try the new leathers prepared—in accordance with the recommendations of the committee appointed by the Society of Arts—to obviate the rapid deterioration of book-binding leathers. It is hoped that British producers will take care to prepare the light leathers specified.

At a sale recently held by Mr. Stevens in King Street, Covent Garden, a great auk's egg in fine condition was sold for two hundred guineas, the purchaser being Mr. Pax. This is a considerable falling-off from the three hundred guineas obtained for the last specimen sold by Mr. Stevens, the reason being attributed to the fact that several other fine examples are in the market. Mr. Pax's specimen was originally bought for two sovereigns. The next highest price obtained at the recent sale was *8l.* 18*s.* 6*d.* for a clutch of four eggs of Bonaparte's sandpiper. For a single egg, the highest price was 27*s.* 6*d.* for one of Pallas's sand-grouse.

Mr. A. W. McCurdy, at a recent meeting of the Canadian Institute, gave an account of his invention of the device for developing photographs without a dark room, now so well known as the Kodak developing machine. It appears that his first idea was to use one solution that would both develop and fix, containing pyrocatechin as the developer. He afterwards employed a combined developer and fixer containing pyrogallol and sodium carbonate to avoid the troublesome caustic alkali. But separate developing and fixing solutions have always been recommended by the commercial makers of the apparatus, doubtless because of the greater certainty when the operations are individually controlled.

The death is announced of Mr. J. N. Tata, the millionaire philanthropist of Bombay. A correspondent of the *Times* points out that Mr. Tata made experiments extending over a series of years for the acclimatisation of Egyptian cotton in India, and in suitable localities these met with some measure of success. In many other directions, notably that of sericulture after the Japanese method in Mysore, the extension of the use of artesian wells and the introduction of cold storage, Mr. Tata contributed to the industrial expansion of the country of his birth. Mr. Tata, by means of his scholarships, tenable by Indian youths of special promise in this country as well as on the Continent and in America, afforded many of his young fellow-countrymen exceptional opportunities for gaining technical knowledge. The Indian University of Research, to be created at Bangalore as the outcome of his offer of an endowment of 200,000*l.*, will be the monument of his beneficent career.

In the death of Mr. Frank Rutley, geological science has lost an enthusiastic worker on rocks and rock-forming minerals—one of the earlier investigators who brought the microscope to bear on petrological studies. His interest in geology was kindled at the Royal School of Mines, but he served as lieutenant in the army for a few years before 1867, when he joined the staff of the Geological Survey under Murchison. After carrying on field work for a time in the Lake District, he began to devote his special attention to the study of igneous rocks, and was transferred to the office in Jermyn Street, where he laboured for a number of years as acting petrologist. In 1876 he described the volcanic rocks of east Somerset and the Bristol district, and subsequently wrote memoirs on the eruptive rocks of Brent Tor and on the felsitic lavas of England and Wales. He was the author of the first English text-book of petrology, "The Study of Rocks" (1879), also of "Rock-forming Minerals" (1888) and "Granites and Greenstones" (1894). He likewise published a very useful handy book of mineralogy which passed through several editions. To the Geological Society he communicated papers relating to perlitic and spherulitic structures, fulgurites, novaculites, &c., and a special memoir on the rocks of the Malvern Hills. In 1881 the Murchison fund was awarded to him by the council of the society. He resigned his post on the Geological Survey in 1882, when he was appointed lecturer on

mineralogy in the Royal School of Mines (afterwards merged in the Royal College of Science). A few years ago he was stricken down with paralysis, and was forced to retire from the public service; but he laboured on as far as his strength permitted with wonderful patience and interest, animated by a cheery nature, and he was able to accomplish much useful work until within about two years of his decease.

WE are glad to find that the study of the meteorological conditions of the Transvaal and Orange River Colony has been taken up seriously by the respective Governments. With regard to the service in the Transvaal, we find some interesting particulars given in *Symons's Meteorological Magazine* for May. The director of the service is Mr. R. T. A. Innes, and the central observatory, which is three miles north-east of Johannesburg, stands at a height of about 5900 feet above sea-level. The grounds cover $10\frac{1}{2}$ acres, and were obtained partly by purchase and partly by gift of a Dutch family named Bezuidenhout. There are already 200 rainfall stations in operation, in addition to about 30 stations of the second and third orders. All the rainfall observers have come forward voluntarily, many of them being farmers and school teachers in thinly populated districts. A weather report is already issued daily, based on observations received by telegraph, and self-recording instruments are on the way to South Africa, and will probably be in working order by the beginning of July.

MESSRS. D. SCHULTE AND CO. have submitted a sample of their self-lighting Bunsen burner, in which the well known property of finely divided platinum igniting under the influence of a stream of hydrogen is employed. The burner proper is of the usual type, but is furnished with a byepass tube at the side, controlled by a cross stopcock. At the top of the byepass, close to the open end of the burner, there is fitted a small bracket holding the bundle of several fine platinum filaments, so constructed that the thin stream of gas from the byepass tube impinges on the stretched wires. A movable metal hood fits over the lighter to direct the pilot flame produced by the action of the platinum to the Bunsen tube, and on turning the stopcock to give full supply, the burner is lighted. The arrangement works very readily, and if the old difficulties with regard to the durability of the delicate portions can be surmounted, the apparatus should be of considerable convenience to laboratory workers.

IN the *Bulletin* of the Johns Hopkins Hospital for March (vol. xv., No. 156), Dr. Eugene Opie writes on the relation of leucocytes with eosinophile granulation to bacterial infection, finding that they are attracted from the blood to the site of the bacterial invasion. Dr. Thomas McCrae gives an interesting biographical notice of George Cheyne, an old London and Bath physician of the seventeenth century. The other papers are of purely medical interest.

THE report of the Inter-Departmental Committee on the Model Course of Physical Exercises has recently been published. The committee was instructed "to examine the model course now in use, to judge how far it should be modified or supplemented, and to consider what principles should be followed, in order to render a model course, or courses, adaptable for the different ages and sexes of the children in public elementary schools." The conclusion arrived at is that the "model course" as at present in use is not completely satisfactory. An elaborate scheme of exercises, no less than 109 in number, has therefore been drafted, and should prove of considerable service to teachers and others.

TWO papers on invertebrates have just been received. In the first Miss H. Richardson (*Proceedings* U.S. Nat. Mus., No. 1369) describes numerous new types of isopod crustaceans collected in Alaska and Hawaii. In the second, which is extracted from the *Mark Anniversary Volume*, Mr. J. H. Gerould discusses certain features in the embryology of the sipunculid annelids, dealing more especially with the structure and homology of the peculiar embryonal envelope and its amniotic cavities.

THE Leishman-Donovan body or parasite has been the subject of a research by Lieut. Christophers (*Sc. Mem. of the Gov. of India*, No. 8). It is met with in India in patients suffering from chronic fever, cachexia, and enlarged spleen. It occurs as a small round or ovoid body 1·5 to 3·5μ in diameter, free or contained within the leucocytes in the liver and spleen and bone-marrow, but not in the muscles or in the peripheral blood. Christophers observed the parasites also in the arachnoid and in ulcers of the large intestine. He agrees with other British observers that the organism is not a *piroplasma*, as stated by Laveran.

IN the April number of the *Journal* of the Quekett Microscopical Club (ix., No. 54), Mr. Julius Rheinberg directs attention to a point concerning the resolving power of a microscopical objective that has been overlooked. As is well known, the numerical aperture of an objective must be of a certain degree in order to resolve a number of equidistant points or lines, and it has been tacitly assumed that the same numerical aperture is required whether the number of lines be two, four, six, or a large number. If, however, there be only two lines, it will be found that they can be resolved with a numerical aperture sensibly less than that required to resolve a large number. The mathematical explanation has been given by Dr. Johnstone Stoney and by Lord Rayleigh.

TWO *Bulletins* have been received from the Experiment Station of the Colorado Agricultural College. In the first Mr. Paddock deals with "crown gall," the name applied to irregular outgrowths which are formed just below the ground at the base of trees, principally fruit trees. It has been referred to the irritation set up by a slime-fungus, and Prof. Toumey has succeeded in developing galls by inoculation. The pamphlet by Mr. Blinn directs attention to the importance of careful selection of seed as illustrated in the case of the Canteloupe.

THE movements of the stomata of leaves is a subject of which Mr. F. Darwin, F.R.S., has made a special study, and the latest paper published in the *Botanical Gazette* furnishes an account of observations made with a Callendar recorder, which is a form of resistance thermometer. Platinum wires are arranged in a zig-zag on plates of talc, and two of these act as "bulbs" against which the leaves are pressed. In general, a withered leaf is used as a control. The results agree with those obtained with the horn hygroscope, and, to quote one instance, the curve produced by severing a leaf shows very clearly the preliminary opening followed by a gradual closing of the stomata.

"INSECTS Injurious to Fruits in Michigan" is the title of an illustrated *Bulletin* issued by the Agricultural College of that State.

IN the course of a paper on metabolism and division in the Protozoa, published in the *Proceedings* of the American Academy, Mr. A. W. Peters points out the important in-

fluence exercised by the particular salt contained in the water on the growth and normal action of free-living cells; cell division in the animalcule Stentor being both accelerated and modified in character by an excess of potassium chloride in a normal medium.

THE London County Council is to be congratulated on the issue, at the price of one penny, of a handbook to the collection in the Horniman Museum at Forest Hill, arranged as an introduction to the study of animal life. Although some of the words and sentences are perhaps a little too technical for the class who will use it, the book forms an admirable guide to the general principles of zoology, and is an honest attempt to put them in a popular guise.

WE have received the prospectus of what promises to be a very useful and interesting work, "The Animals of New Zealand," by Messrs. Hutton and Drummond. As it deals only with the air-breathing vertebrates of the colony and its coasts, the bulk of its contents will be devoted to birds. Another faunistic work on our table is the second part of the Boston Society's "Fauna of New England," containing the Batrachia, drawn up by Mr. S. Henshaw.

THE contents of the February number of the *American Naturalist* are restricted to four articles, of which three are devoted to the lower vertebrates. In the first, Prof. H. F. Osborn emphasises in popular language his views with regard to the classification of reptiles, in the course of which he urges the propriety of forming families on phylogenetic lines. He would, for instance, include the Eocene Hyracotherium in the horse family (Equidæ), while a closely allied contemporaneous genus is included among the tapirs. The early stages in the development of an American salamander (*Desmognathus fuscus*) form the subject of a communication by Prof. Wilder, while Miss Townsend discusses the histology of the light-organs of the fire-fly *Photinus marginellus*. Apparently the author accepts the view that the latter organs are modified fat-bodies. Finally, Mr. E. G. Mitchell points out the relation of the breathing valves in the mouths of bony fishes to the shape of the mouth itself.

A USEFUL summary of the metalliferous mining in Ireland has been contributed by Mr. G. H. Kinahan to the *Transactions* of the Institution of Mining Engineers.

WE have received the annual report of Mr. H. B. Kümmel, State Geologist of New Jersey. It includes accounts of floods, forest fires, and underground waters, and reports on iron, zinc and copper mining, and on the Portland cement industry.

WE have received the *Transactions* of the Geological Society of South Africa, vol. vi., parts i. to vi., a well illustrated and clearly printed volume, dealing, as might be expected, largely with the metalliferous and coal deposits, and also with petrological questions. Mr. J. P. Johnson contributes a paper on the discovery of implement-bearing deposits in the neighbourhood of Johannesburg. In high-level drift near Roodekop Farm he has found water-worn implements of quartzite of Eolithic type, much resembling those of the plateau gravel of the Thames basin. At lower levels, along the bottom of the Bezuidenhout valley, he obtained implements of Palæolithic type, the deposits being evidently of later date than the high-level drift. Elsewhere he has found implements of Neolithic type. In his opinion the facts indicate that "South Africa saw much the same evolution in the culture of its Stone age as did that of the Thames basin and the rest of Britain and Western Europe." The fossil flora of Vereeniging is treated of by Mr. T. N. Leslie, who, aided by the researches of Mr. A. C. Seward, gives revised lists of the plant remains from the Permo-Carboniferous strata.

THE Permian fossils of the central Himalayas are described by Dr. Carl Diener (*Mem.* Geol. Survey India, series xv., vol. i., part v., 1903). In previous parts of this volume, Nos. 2 to 4, the fossils obtained by the Geological Survey up to the year 1893 from the "Anthracolithic series" (Permian portion) were described. In the present work Dr. Diener deals with specimens collected during the years 1898–1900. Under this method the fossils are treated according to their stratigraphical horizon and locality. The localities include Chitichun, Malla Sangcha, the Lissar Valley, Byans, and Spiti. In Spiti the Anthracolithic system is divided into two groups separated by a great unconformity—the upper group is regarded as Permian, and the lower as of Upper Carboniferous age. In the Permian system, to which attention is now directed, two facies are recognised in the Himalayas, and these differ in lithological and faunistic characters. One facies is represented by the white and red limestones of Chitichun and Malla Sangcha, and it corresponds with the topmost zone of the middle Productus limestone of the Salt Range and with the Tibetan series. In the other facies, developed in the main region of the Central Himalayas, the Permian strata comprise dark shales and calcareous sandstones; the fauna is composed of cephalopods, lamellibranchs, gasteropods and brachiopods, while corals and Bryozoa are wanting, and the majority of the leading fossils are autochthonous species, none of which has been found outside the Himalayas. Only a small percentage of species is identical with Salt Range forms, and the affinities with the Tibetan facies are less distinctly marked.

THE account of the genus Diospyros, contributed by Mr. H. Wright to the *Annals* of the Royal Botanic Gardens, Peradeniya, constitutes a monograph of the Ceylon species. *Diospyros Ebenum*, which is the main source of ebony-wood in Ceylon, is found both in the dry and wet regions of the island, and is considered to be ready for felling when the tree has attained a breast-height circumference of 9 feet. The different species vary considerably in the colour of their heart-wood; in *D. Ebenum* the black heart-wood owes its colour mainly to chemical and physical changes of the materials stored in the elements of the wood, and to a less degree to a change in composition and colour of the cell walls. Considerable variation occurs also in the types of flowers, and in *D. Ebenum* the flowers may be diœcious, monœcious, or polygamous.

IN the *Proceedings* of the Royal Dublin Society, Dr. T. Johnson describes a fungal disease which was found upon the willows known as "black mauls" growing in osier beds in Connemara, and identifies the fungus as *Physalospora gregarina*, a member of the Sphæriaceæ. The willows were growing on poor and sour land, and owing to their impoverished condition were especially liable to the attacks of the fungus.

THE development of scientific investigation and methods in connection with the agriculture of the West Indies has been a prominent feature in the policy of Sir D. Morris, the Commissioner of Agriculture, and an instance of the valuable work which is being carried on is furnished by the reports on sugar cane experiments which have been conducted at Antigua and St. Kitts under the super-

intendence of Mr. F. Watts. The first part deals with the cultivation of selected varieties of canes grown in the same way as the ordinary crops on the estate. The Barbados seedling B. 208 again heads the list, both in the matter of providing the heaviest canes and producing the purest juice; at the same time it retains its excellent character as a ratoon cane. Another set of experiments, continuing the work of former years, deals with the question of manuring. The evidence is opposed to the value of artificial manures for plant canes when the land has been well prepared with pen manure, but for obtaining maximum crops with ratoons the addition of nitrogenous salts is necessary.

THE first part of vol. i. of the new series of the *Transactions of the Natural History Society of Northumberland, Durham, and Newcastle-upon-Tyne* has now been issued. Among other interesting contents may be noticed "Notes on Entomostraca Found at the Roots of Laminariæ," by Dr. G. S. Brady, F.R.S., and papers by Mr. Clephan on ancient Egypt, and by Mr. Alex. Meek on the fishes of the north-east coast.

THE seventieth annual report of the Bootham School (York) Natural History, Literary, and Polytechnic Society, a copy of which has been received, affords abundant evidence of the importance attached by the masters of this school to the development in boys of an interest in practical work in science and in open-air study of natural phenomena. The report should be seen by science masters in secondary schools where little is done to create and foster interest in personal observations of nature.

THE British Fire Prevention Committee has issued, as number eighty-one in its series of publications, a descriptive paper by Mr. Edwin O. Sachs on the fire at the Iroquois Theatre, Chicago, on December 30, 1903. The publication also contains the new theatre regulations at Chicago, and notes on constructional particulars by the U.S.A. National Fire Protection Association. It appears that the stage of the Iroquois Theatre was of the ordinary type with the usual wood equipment. The stage accessories, scenery, properties, &c., were of the ordinary highly inflammable character, and had been in use for a considerable time, which involved the usual fraying and high grade of inflammability. The electric arc lamps used on the stage were not properly enclosed or suitably protected, and the fire appliances and exits were equally unsatisfactory. Mr. Sachs, after reviewing the whole circumstances of the fire, gives a number of general conclusions which deserve attention. He insists that fire prevention on the stage—where the Iroquois fire originated—can only be obtained by suitable incombustible construction and equipment. The scenery, properties, and furnishings of the stage must be thoroughly impregnated, so that they do not catch or spread fire by any spark or flame. When it is remembered that this Chicago fire resulted in 572 deaths, it is not too much to demand that city authorities should make the best use of the means provided by science to prevent such outbreaks of fire.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN JUNE:—

June 1. 12h. Jupiter in perihelion.
5. Ceres in opposition to the Sun. Ceres mag. 7·4.
,, 14h. 13m. to 16h. 30m. Transit of Jupiter's Sat. III. (Ganymede).
8. 8h. Mercury at greatest elongation, 23° 46′ W.
9. 12h. 34m. Minimum of Algol (β Persei).
12. 9h. 23m. ,, ,, ,,
15. Venus. Illuminated portion of disc = 0·994, of Mars = 0·999.
18. Saturn. Major axis of ring = 41″·62. Minor axis = 9″·73.
19. 5h. Uranus in opposition to the Sun.
24. 11h. 55m. to 12h. 30m. Moon occults θ Libræ (mag. 4·3).
29. 17h. Venus in conjunction with Neptune, ♀ 1° 24′ N.

COMET 1904 *a*.—In No. 3947 of the *Astronomische Nachrichten*, Prof. Strömgren publishes a new set of parabolic elements, and a daily ephemeris extending from May 18 to June 19, for comet 1904 *a*. The following is taken from his ephemeris:—

12*h*. (*M.T. Berlin*).

1904		α h. m. s.	δ ° ′	log *r*	log Δ	Brightness

In No. 3946 of the same journal, Prof. Pickering reports that on a spectrogram taken with an objective prism at the Harvard College Observatory on April 16, the nearly continuous spectrum shows a slight increase of intensity at two points, the distribution of the light being the same as that recorded on a similar spectrogram of comet 1898 VII.

The comet was independently discovered by M. Lucien Rudaux at his private observatory at Donville (Manche) on April 16. Using a portrait lens of 4 cm. aperture, he photographed the region about the nebula M92 with an exposure lasting from 10h. 15m. to 10h. 45m. (Paris M.T.), about 4 hours before Mr. Brooks discovered the comet at Geneva (U.S.A.). On developing the plate he discovered an unknown nebulous patch to the north of the nebula, but cloudy weather prevented him from confirming his discovery (*Astronomische Nachrichten*, No. 3946).

THE STABILITY OF SOLAR SPECTRUM WAVE-LENGTHS.—In a paper published in No. 19 (1904) of the *Comptes rendus*, M. Hamy again refers to the apparent change of wave-length of the green cadmium line at λ 508, with the conditions under which the radiation is produced. He states that on increasing the temperature surrounding the vacuum tube from 295° to 310° C., the relative intensities of the single line and the doublet, referred to by Prof. Fabry (*Comptes rendus*, cxxxviii. p. 854), are considerably modified, so much so that the mean wave-length is appreciably altered.

He then suggests that a change of mean wave-length of this character may largely affect the stability of the wave-lengths of lines in the solar spectrum, because the conditions of radiation in the solar atmosphere are probably considerably modified during the various epochs of solar disturbance.

VARIABLE STAR OBSERVATIONS.—The variable star observations made at Rousdon by the late Sir Cuthbert Peek have been edited by Prof. H. H. Turner, and the work is now ready for press. At the meeting of the Royal Astronomical Society held on April 8, Prof. Turner stated that on subjecting the few available light curves to harmonic analysis, he found that the different harmonics appear to form a regular series. Another point of interest discovered was that on subjecting the sun-spot activity curve, obtained by plotting Wolf's numbers, to similar analysis, the coefficients fitted fairly well into the formulæ obtained from the Rousdon star variations if the sun-spot *maxima* be taken as corresponding to the variable star *maxima* (*Observatory*, No. 344).

PROVISIONAL RESULTS OF THE INTERNATIONAL LATITUDE SERVICE.—Prof. Albrecht publishes in No. 3945 of the *Astronomische Nachrichten* the provisional results obtained by the International Latitude Service during 1903–4. From a diagram and a table, which show the variation of the momentary pole from the position of the mean pole, it is seen that the amount of this variation increased during 1903, and is now probably near its maximum value.

THE TISSUE-LYMPH CIRCULATION.[1]

AFTER paying a warm tribute to the memory of his teacher in physiology, the late Prof. Sharpey, F.R.S., the lecturer proceeded.

I propose to submit to you the results of a study on the circulation of the tissue fluid in man, or, in other words, on the fluid transfers between the blood and the tissues. Apart from its intrinsic physiological interest this subject has important bearings on the practice of medicine.

Some of the conclusions suggested to me by this inquiry

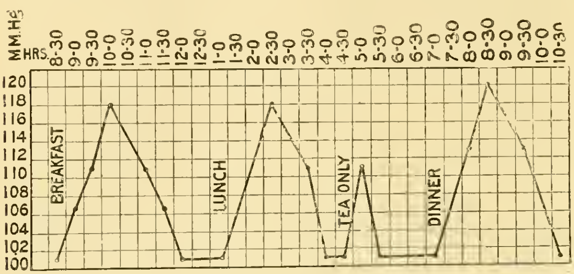

FIG. 1.—Chart showing rise of arterial pressure after food.

were so unexpected that I was naturally led to repeat my observations in every department of it over and over again, and to scrutinise all the facts with more than ordinary diligence. More than 3000 observations have been made in health and disease, but I propose in these lectures to use mainly the physiological material.

METHODS AND APPARATUS.

[Dr. Oliver here described the methods and apparatus employed with certain improvements in the hæmocytometer, hæmoglobinometer, and hæmodynamometer.]

THE EFFECT OF THE INGESTION OF FOOD ON THE TISSUE-LYMPH CIRCULATION.

Elsewhere[2] I have shown that the ingestion of food initiates an interesting series of variations in the blood and blood pressures which culminates in a prolonged wave-like exudation of tissue-lymph, and that this excitation in the circulatory system recurs with perfect regularity after each meal. Subsequent inquiry has amply confirmed this position.

The digestive variations in the blood pressure.—The ingestion of food invariably raises the arterial blood pressure (Fig. 1). In an hour after a meal it rises 15 or even 20 millimetres of mercury, then it begins to fall, and in from two and a half to three and a half hours it becomes stationary until the next meal or until exercise is taken. The curve of the venous pressure rises and falls throughout with that of the arterial pressure. It may, I think, be inferred from these facts that the capillary blood pressure follows the same curve after meals, for we know that this pressure is more closely related to the venous than to the arterial, and that if both these pressures rise or fall together we may fairly assume that the capillary pressure will also rise or fall. After food the pulse-rate also increases, and in an hour it may have gained from eight to fifteen beats a minute. When the pulse pressure gauge is applied so as to arrest the pulsation of the radial artery (the finger being used as the indicator), the reading becomes cardiometric, and is generally increased in an hour after a meal from 15 to 20 millimetres of mercury. Therefore it would seem that digestion very considerably stimulates the heart, augmenting the output and the contractile energy of the ventricle.

The essential aim of the digestive excitation of the circulatory system is to raise the capillary blood pressure, and according to my observations this end is attained by the increased activity of the cardiac muscle. But it can likewise be secured by taking with a meal some substance which dilates the arteries and arterioles, and thus lowers the arterial pressure; then the venous pressure is greatly increased, and the capillary pressure must be raised, being between two pressures higher than the normal capillary pressure.

We may therefore infer that we may have a rise in the capillary pressure either with an increase or a decrease of the arterial pressure according as we have cardiac stimulation (as after meals) or vaso-dilation.

DIGESTIVE VARIATIONS IN THE BLOOD.

I have followed three series of alterations in the blood during digestion, namely, in the corpuscles, in the hæmoglobin, and in the specific gravity. As the variations in the chromocytes and in the hæmoglobin are identical, they are taken together.

Digestive variations in the corpuscles and haemoglobin.—The finger, having been subjected to the compression of the rubber rings, yields blood which shows a progressive rise in the percentages of the corpuscles and of the hæmoglobin until an hour has elapsed, when the increment amounts to from 8 to 10 per cent.; then the percentages gradually fall,

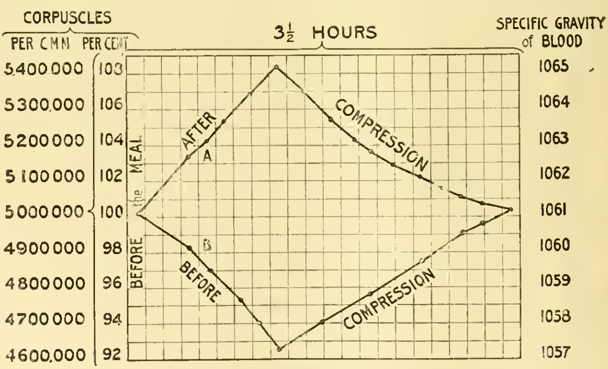

FIG. 2.—Chart showing the percentages of corpuscles and the specific gravity of the blood before and after compression. Observations made before a meal and at frequent intervals afterwards.

and they finally settle down to normal in from two and a half to three and a half hours (Fig. 2, A). Should, however, the blood be derived from the finger in the ordinary way (without compression), the successive readings of the blood elements indicate a progressive fall in the percentages, which in an hour amounts to from 6 to 8 per cent., when a rise sets in and recovery is eventually established (Fig. 2, B).

Digestive variations in the specific gravity of the blood.—The blood, as shown by compression of the finger, rises in

[1] Abstract of the Oliver-Sharpey Lectures on Recent Studies on the Tissue-lymph Circulation, by Dr. George Oliver. Delivered before the Royal College of Physicians of London on April 12 and 14.

[2] *Proceedings* of the Royal Society, June 11, 1903; *The Lancet*, October 3, 1903, p. 940; and the *Journal* of the British Balneological and Climatological Society, 1903.

specific gravity after meals, the rise reaching its maximum point (*e.g.* from 1061 to 1065) in an hour. The specific gravity then begins to fall, settling down to the initial point at the conclusion of the wave-like disturbance (Fig. 2, A). On the other hand, the blood derived from the finger uncompressed affords a specific gravity which follows the contrary course, that is to say, it falls and then rises (Fig. 2, B). When the digestive disturbance is over, the variations in the blood, like those in the circulation, cease, and the readings in normal subjects at rest continue to be alike in both samples (before and after compression) until the following meal.

The digestive exudation of tissue lymph.—On reviewing the foregoing data it is obvious that they indicate strictly concurrent events. All the four series of variations follow exactly the same curve. What is the link which binds them together? If we suppose that the ingestion of food in some way raises the capillary blood pressure which exudes a filtrate of a portion of the liquor sanguinis into the areolar spaces, all the changes in the blood which I have described will naturally follow (see Fig. 2). In proportion to the exudation under a rising capillary blood pressure, the blood will become more and more concentrated in chromocytes and in hæmoglobin, and inasmuch as its specific gravity mainly depends on the corpuscles, the density of the blood will rise *pari passu* with the increased concentration. Then, when the capillary pressure begins to fall, as it does after the acme of the digestive disturbance has been attained, the concentration of the blood diminishes, and we may assume that either absorption of the watery elements of the effused lymph overbalances exudation or that the effusion is being returned by the lymphatics to the blood. Now I have shown that none of these alterations in the blood could have been ascertained by the examination of blood derived from the finger in the ordinary way; they only become apparent after the compression of the tissues by the rubber rings, which removes the extra-capillary fluid and enable us to obtain the blood undiluted by that fluid. But the progressive readings of the ordinary samples of blood, though valueless, and actually misleading when accepted as independent testimony of blood changes during digestion, become instructive when compared with the readings of samples obtained after compression, for they then afford a measure of the amount of fluid withdrawn from the blood. The differential readings of the hæmocytometer tubes made every fifteen minutes after a meal show the greatest divergence, and therefore the largest quantity of tissue fluid, just at the time (an hour after a meal) when the digestive blood pressure wave and the concentration of the blood attain their maximum development. The difference, indicated by the scale on the tubes, will amount to from 15 to 20 per cent.; it will then gradually diminish, and will finally disappear in from two and a half to three and a half hours, and will not reappear until after the next meal or until exercise is taken. The amplitude and duration of the lymph wave are influenced by various conditions, such as the tone of the subject, the bulk and nature of the meal, the use of beverages, rest, or exercise.

Other rhythmical digestive variations.—I will now direct your attention to other physiological variations produced by the ingestion of food, synchronous with the foregoing. These are:—(1) the digestive curve of augmented respiratory exchange determined by Fredericq and other observers; (2) the gastric juice curve of Pawlow; and (3) a digestive rhythmical variation of muscular contractility, which came to light while studying the effects of muscular tension on the arterial pressure. It was found that when tissue-lymph was not apparent (*e.g.* before meals), the tension raised the arterial pressure to a maximum degree (*e.g.* 40 mm.), whereas when the lymph was fully effused (an hour after a meal) the pressure could only be slightly raised (5 or 10 mm.). The digestive curve of muscular contractibility (*i.e.* the capability of being contracted) is therefore the reverse of the lymph curve, and it is inferred that the exudation of the lymph into the muscular tissue checks the shortening of the muscular fibres, and thus diminishes the effect of their contraction on the intramuscular vessels.

These observations on the condition of the muscles during digestion, therefore, confirm the teaching as to the outflow and absorption of lymph furnished by the differential examination of the blood. At the termination of the digestive disturbance there is apparent a gain in the contractile energy, as expressed in an additional rise of the arterial pressure produced by muscular tension. This gain (which only becomes evident after the absorption of the lymph) varies from 5 to 20 millimetres, according to the nature of the food consumed and the need for recuperation.

The effects of typical meals on the digestive lymph flow.—Let us now study the digestive curves of lymph exudation produced by four different kinds of meals. First, the ordinary mixed meal containing the usual proportions of animal food, vegetables, and farinacea; secondly, the meat meal, consisting of animal food in various forms, with cheese and butter and a very little toast; thirdly, the vegetable meal, with farinaceous puddings, fruit, and cheese; and fourthly, the milk meal, milk, bread, and farinaceous puddings. In each case the fluid supplied was a tumbler of water, and the amount of food was merely limited by a feeling of satisfaction. Sugar and salt (two grams of each) were taken in the same quantity at all the solid meals. The meal was at one o'clock, and the same subject was throughout submitted to observation. No exercise was permitted for an hour before and after meals, nor until the digestive disturbance had quite subsided. Observations were made just before the meals and every fifteen minutes after them. The results are epitomised in the following table (Table I.):—

TABLE I.

The meal	Lymph effusion: Maximum per cent.	Lymph effusion: Duration hours
Roast meat	30·0	5
Mixed	17·5	3
Vegetable	12·5	3
Milk	7·5	$1\frac{1}{2}$

You see that the lymph curves produced by these several kinds of meals vary enormously in amplitude and length, and in the following descending order:—meat meal, ordinary meal, vegetable meal, and milk meal. The net gain in muscle contractility shown by the tension test after the subsidence of the digestive disturbance and the removal of the lymph is in the same order, expressed by the following figures:—15 (meat meal), 10 (ordinary meal), 7 (vegetable meal), and 3 (milk meal). Some light will be thrown on these results by studying the effect of the separate food elements.

The effect of the food elements on the production of tissue lymph.—I will first mention those substances which, according to my observation, do not alter the blood pressure or cause the flow of tissue lymph:—cold water, starch, fats, gelatin, proteid as represented by myosin or egg-albumin, the sugars (cane sugar, glucose, maltose, galactose, mannose, dextrose, and inulin), pepsin, and hydrochloric acid. Cold water (*e.g.* 500 cubic centimetres, or a little more than 16 ounces) has no effect, but the same amount of warm water lowers the arterial pressure. This is therefore a temperature effect. In regard to proteids, I selected chemically pure myosin (muscle proteid) and white of egg as representative of the group. So far their effects have been negative. In support of this conclusion we have also the fact that the lymph exudation produced by a meal of roast beef is 30 per cent., whereas that caused by a meal of boiled meat is only 7 per cent. All the sugars named also produce negative results. There are, however, other sugars (glycogen, lævulose, and lichenin) which have been found decisively to affect the blood pressure and the flow of lymph.

Inorganic salts.—I will here only refer to sodium and potassium chlorides, as my observations on the effects of other salts are not sufficiently advanced for publication. Sodium chloride, in percentages varying from 1·5 to 2·0, invariably raises the arterial pressure and increases the outflow of tissue lymph; four grams produce in thirty minutes the exudation of 15 per cent. lymph, which is completely absorbed in thirty minutes more. Potassium chloride lowers the arterial pressure, four grams producing a fall of from 10 to 12 millimetres of mercury. Sodium chloride increases and potassium chloride diminishes the digestive curves. When these two salts are taken in equal proportions—*e.g.* two grams of each—their effects on the blood pressure and lymph flow neutralise each other.

Muscle extractives.—The lymph exudation produced by home-made beef-tea, derived from half a pound of beef infused first in cold water and then in hot, is similar in amplitude to that of a meat meal (see *supra*), only it is of shorter duration. Two well known beef extracts, selected out of several as typical of the rest, gave a somewhat smaller amount of lymph exudation, the quantities taken being those directed by their proprietors. No salt or other seasoning was added to the preparations. The following products derived from muscles have been administered, dissolved or suspended in six ounces of cold water:—creatin, creatinin, xanthin, hypoxanthin, uric acid, carnin, and glycogen.

[Dr. Oliver here described how the matter of dosage was settled.]

The doses thus worked out may seem to the experimental physiologist to be absurdly small, but the uniform results obtained in different subjects showed that it was not necessary to experiment with larger quantities. My observations show that uric acid (either as uric acid or as ammonium urate), xanthin, creatinin, carnin, and glycogen produce a decided rise in the blood pressures (arterial, capillary, and venous) and increase the exudation of tissue lymph, the pressure and the exudation rise being proportionate to each other. This effect from ingesting glycogen was quite unexpected. The accompanying table gives the doses, the maximum lymph exudation and arterial pressure, and the duration of these effects.

TABLE II.

	Maximum rise		Duration of effect in minutes
	Lymph per cent.	Arterial pressure mm. Hg	
Carnin, gram 0·0325 (½ grain)	15	115	30
Creatinin, gram 0·0325 (½ grain)	14	114	30
Glycogen, gram 0·0325 (½ grain)...	6	106	23
Ditto, gram 0·13 (2 grains)	20	120	90
Uric acid, gram 0·0325 (½ grain)...	17	117	85
Ammonium urate, gram 0·13 (2 grains)...	25	125	110
Xanthin, gram 0·0325 (½ grain)	20	120	105

A long latent interval (about twenty minutes) elapsed after swallowing uric acid or ammonium urate and xanthin before any effect on the blood pressure was apparent, a fact which may be accounted for by the low solubility of these products, which, however, produced effects more decided and more prolonged than those which followed the other products. Creatin and hypoxanthin differ from the other allied products in their effects on the arterial pressure. Creatin produces at first a fall which is followed by a rise, and hypoxanthin causes a marked fall in the arterial and an equally decided rise in the venous pressure.

When xanthin is combined with it in equal parts, the blood pressures remain unaltered. In like manner when creatinin is taken with creatin (equal parts) the preliminary fall of arterial pressure produced by creatin fails to appear, and the effects of the two agents balance each other for twenty minutes, after which the rise of creatinin combined with the ultimate rise of creatin take their normal course. All the muscle-derived products raise the capillary blood pressure, increase the exudation of tissue lymph, and are cardiac stimulants.

The active principles contained in beverages.—Allied to most of the foregoing products in their chemical constitution and physiological action on the blood pressure and lymph circulation are the active principles of tea, coffee, and cocoa, caffein and theobromin being methylxanthins, the former being called tri- and the latter di-methylxanthin. They are therefore bodies with a purin basis (C_5N_4), and, like most of the other purin bodies, they raise the blood pressure in a long, well sustained curve, with an accompanying wave-like exudation of tissue lymph, and they are also like the other purins in being cardio-stimulants.

The effects of alcohol on the blood pressure and lymph circulation are modified very considerably by the presence of other constituents in spirits, wines, malt liquors, &c. The arterial pressure curve of absolute alcohol at first falls and then rises, the fall below the normal being equivalent to the rise above it. It therefore resembles that of creatin, and differs from that of xanthin, uric acid, creatinin, and glycogen.

Whisky follows the compound curve of absolute alcohol; brandy, wines, and beer conform to the simple curve of the bodies just mentioned, and gin follows the curve of hypoxanthin, this marked difference being due to the juniper it contains.

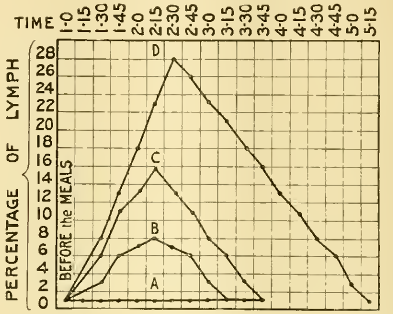

FIG. 3.—A, lymph record from purin-free meal. B, purin-free meal with sodium chloride 2·0 grams. C, purin-free meal with sodium chloride 4·0 grams. D, purin-free meal with sodium chloride 2 grams and uric acid 0·016, creatin 0·033, creatinin 0·033, xanthin 0·016, hypoxanthin 0·016, and glycogen 0·048.

I conclude from the foregoing data that caffein, theobromin, and the alcoholic beverages (but more especially brandy, wines, and malt liquors) excite the flow of tissue lymph like the purin and the other products previously mentioned.

HOW IS THE DIGESTIVE EXUDATION OF TISSUE LYMPH PRODUCED?

We are led by the foregoing data to the following conclusions:—(1) That the food constituents themselves (proteids, fats, and carbohydrates) do not possess the power of starting the mechanism by which lymph is dispensed to the tissues throughout the body. (2) That nature, however, associates with our food-stuffs small quantities of certain very active substances which bring into play that mechanism, though these substances themselves are practically devoid of food value; and that man frequently increases this natural lymph stimulation by the use of salt and beverages containing bodies which also incite the flow of lymph.

But let us put this matter to the test of experiment. It is possible to arrange a meal containing a fairly large quantity of nutrient elements in such a way that it will not react on the circulation at all, and will not induce the flow of tissue lymph. Such a meal consists of three or more eggs, a full supply of white bread, boiled rice or tapioca, cream, sugar, and cheese, with a tumbler of cold water. I have taken this meal several times with the feeling of repletion, and yet it has not produced a rise of blood pressure or the slightest flow of tissue lymph.

In Fig. 3 A shows the negative effect of this meal on the tissue lymph; B and C indicate two exudations produced by adding two and four grams of sodium chloride to the meal; and D is a voluminous lymph wave resulting from the addition of a mixture of the following products with two grams of salt:—uric acid, 0·016 gram; creatin, 0·033 gram; creatinin, 0·033 gram; xanthin, 0·016 gram; hypoxanthin, 0·016 gram; and glycogen, 0·048 gram. The meal produced a much more refreshing and sustaining effect when the digestive lymph flow was excited by the addition of salt, and more especially by that of salt associated with the physiological products than when taken alone.

Exercise.

The fundamental effects of exercise on the blood pressure may be readily studied in an epitomised form by placing the pad of the hæmodynamometer over a small superficial artery, like the superficialis volæ, and then throwing all the muscles into a state of tension for sixty seconds (the arm on which the observation is made being excluded from the contraction). In Fig. 4 you observe that the complete arterial pressure curve of muscular contraction is made up of two elevations, (A) primary and (C) secondary, separated by a fall (B) which is just as decidedly below the normal pressure as the second rise is above it. The first elevation (A) is synchronous with the tension, and the second (C) appears after the muscles are relaxed.

Now these oscillations of the arterial pressure are all seen on a larger scale in ordinary exercise, each stage being, of course, prolonged in proportion to the duration of the exercise. The primary rise is invariably followed by a gradual fall, even during the continuance of the exercise, and by a rapid and decisive fall on its cessation, and that fall is succeeded during rest by a second rise.

Sir Lauder Brunton and Dr. Tunnicliffe are, I believe, the only observers who have furnished trustworthy data on the blood pressure in man, both during muscular movement and immediately after its cessation, and their data accord with my own.[1]

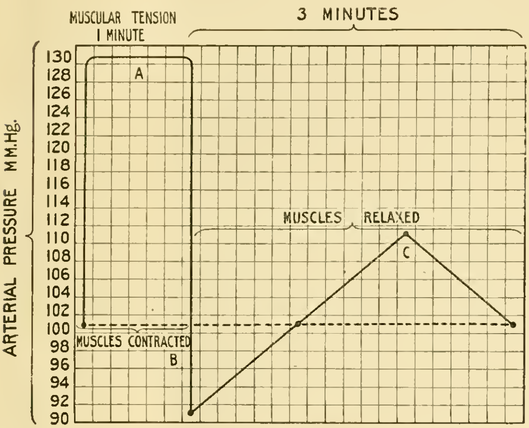

Fig. 4.—The effect of muscular tension on the arterial pressure; (A) rise from muscular tension; (B) fall on relaxing the muscles; (C) secondary rise during rest.

The secondary rise of blood pressure which I have invariably found to supervene during rest after exercise does not, however, seem to have been recognised by other observers.

Exercise invariably increases the exudation of tissue-lymph. Inasmuch as it is rapidly absorbed on the cessation of exercise, the observation must be made without delay.

How are these effects of exercise produced? According to Ludwig and Gaskell (Ludwig's "Arbeiter," 1877), during a short tetanus the flow from the efferent vein of the muscle, after the first spurt of blood, may fall to practically *nil*. Therefore we may infer that muscular contraction causes partial or temporary occlusion of the intra-muscular vessels, and that this increase of peripheral resistance, along with reflex cardiac stimulation, will go far to explain the rise in the arterial pressure.

At the same time, the capillary pressure within the muscle will fall, and lymph will not be exuded. But the state of the circulation is different in the non-muscular parts, for all the blood pressures (arterial, capillary, and venous) are markedly raised during the sustained tension of the muscles. Hence the effusion of lymph in the finger. On the other hand, when the contraction ceases, the intra-muscular capillary pressure will rise, and lymph will then be effused into the muscles. That the muscles when relaxed after contraction become full of blood is shown by the work of Ludwig and his pupils, and by Sir Lauder Brunton and Dr. Tunnicliffe, who have furnished graphic evidence of the dilatation of the intra-muscular arteries which follows contraction (*op. cit.*).

As after food so after exercise the contractibility of the muscles (as indicated by the tension test) diminishes in proportion to the amount of lymph effused.

Exercise likewise provides us with some instructive facts as to how tissue-fluid is removed. Observation has shown that a short muscular contraction of sixty seconds will produce two effusions, one during the contraction which is entirely absorbed in sixty seconds, and another which is immediately afterwards thrown out, and disappears just as quickly, so that in four minutes we have two successive effusions which entirely clear up. The rapidity with which lymph disappears from the tissues in a state of rest certainly favours the notion of absorption rather than that of transmission along the lymphatics. Now, experimentation on animals has shown that muscular action of some kind is necessary to ensure a flow of lymph along the lymphatics, so we may conclude that during exercise the muscular action will more particularly favour that passage for the lymph.

Fatigue.

Observation has shown that the rise in the arterial pressure produced during the continuance of exercise becomes less and less pronounced in proportion to the duration of the exercise; for example, the initial increase of from 15 to 20 mm. gradually subsides until, after the lapse of a certain time (which varies with the tone of the individual and with the external temperature), the arterial pressure will not exceed 100 mm. Hg, and if the exercise is further continued it will even fall lower, to 95, 90, or 85 mm. This point was also observed by Sir Lauder Brunton and Dr. Tunnicliffe.

Why should the rise of pressure, normally induced by exercise, be effaced or even replaced by a fall when exercise is prolonged?

Inasmuch as the lymph exuded during exercise obstructs the contractile pressure of the muscular fibres on the intra-muscular arteries and arterioles, the peripheral resistance caused by exercise will be reduced, and the arterial pressure will gradually fall. In fatigue, no amount of will exerted over the muscles can raise the arterial pressure at all; the muscles, though capable of ordinary contraction, become, as it were, lymph-logged. But massage quickly disperses the lymph, and the contractibility is restored. Human instinct, without knowing the "why," practised what is now taught by physiological inquiry. We read in the "Odyssey" how the women rubbed and kneaded their weary heroes returned from battle, and thus invigorated them, and we know that from time immemorial rubbing was the sovereign remedy for fatigue.

The physiology of fatigue includes another important factor, namely, diminished gravity control over the blood pressure. The outcome of exercise is the production of hypotonia in the vaso-motor mechanism, which is the central fact, as it were, of fatigue.

Rest.

During rest after exercise there is developed a steady and persistent rise of the blood pressures and a corresponding effusion of lymph, and the volume and duration of this second outflow of lymph are always proportionate to the vaso-dilator or reducing effect of exercise. The physiological intent of it is to repair and recharge the muscles,

[1] "Remarks on the Effect of Resistance Exercises upon the Circulation in Man, Local and General," by Sir Lauder Brunton and F. W. Tunnicliffe, M.D. (*Brit. Med. Journ.*, October 16, 1897.)

for after the lymph is absorbed the contractibility is always found to be restored. How are the muscles thus automatically renovated without food? It seems highly probable that the reparative lymph exudation which follows exercise is produced by the agency of chemical substances generated by muscular contraction, just as the digestive lymph flow is caused by exogenous lymphagogues. Creatin and lactate of ammonium produce the double curve of arterial pressure induced by exercise and rest.

Sleep.

A large volume of lymph (not less than 20 per cent.) is exuded into the somatic tissues during sleep.

In sleep the arterial pressure falls very low (from 78 to 82 mm. Hg) and the venous pressure rises to a high point (40 to 50 mm. Hg). There is complete physiological vaso-motor relaxation, consequently the veins not only of the somatic, but of the splanchnic area are filled with blood. The splanchnic stasis is shown by the fact that when a weight (a shot bag of 14 lb.) is applied to the abdomen, the arterial pressure is raised at once from 80 to 100 mm. Hg. In a few minutes, however, when the subject is fully awake, the arterial pressure rises to 95 mm. Hg or so, the venous pressure falls to 15 or 20 mm. Hg, the shot bag no longer raises the arterial pressure, and the effused lymph of sleep, having become absorbed, is no longer apparent.

What is nature's intent in thus supplying the tissues so liberally with lymph during our sleeping hours? The answer admits of no doubt—restoration; and how true to fact is the old proverb, "He who sleeps, dines"! For during sleep nature provides the maximum amount of tissue-lymph, which we only obtain intermittently after meals. Can this be proved? The answer is provided by the tension test.

[Dr. Oliver here epitomised the results of a night and morning record, demonstrating in figures the restorative power of sleep.]

[The effects of gases (oxygen, carbonic acid, sulphurous acid, sulphuretted hydrogen, and the atmosphere of sewers), of gravitation, of temperature, and of internal secretion (supra-renal, thyroid) on the tissue-lymph circulation were described, and the vexed question as to whether tissue-lymph is a secretion or a pressure product was discussed.]

Is there an intermediary circulation?—The rapid removal of lymph from the tissues when the muscles are at rest, for example, after exercise and on awaking from sleep, suggests absorption rather than transmission by the lymphatics. Therefore I think there is evidence in support of a circulation of fluid independent of the lymphatic circulation, though controlled by the capillary circulation, of which it may be said to be an extension.

There is not time to discuss the forces involved. The best account of them, as at present known, is that given by Prof. Starling, of University College, than whom no one has done more valuable work in support of Ludwig's pressure theory (Schäfer's "Text-book of Physiology," vol. i.). Ludwig pointed out that the prime factors in the effusion of lymph are filtration and diffusion. My observations refer only to filtration, and they suggest such a scheme of the intermediary circulation as is represented in Fig. 5, which shows the mechanism, as it were, for the supply of pabulum to the tissues (AA) and for the removal of soluble waste from them (BB). The view there represented explains why the ingestion of food restores the tissues at once, and long before the food itself can be assimilated into the blood. The exhausted tissues have not, therefore, to remain unsupplied until the food becomes part of the common store of pabulum, which the blood keeps ready for distribution. Each supply of food may be viewed as a deposit paid to our banking account, but it is not merely a deposit, for nature combines with it a cheque for payment; the banker therefore is compelled to reimburse at the same time that he receives, so that the balance is kept fairly uniform.

In normal subjects each effusion of tissue-lymph is intermittent, rising out of and subsiding into an apparently lymph-free state of the tissues when the capillary blood-pressure (as indicated by the venous pressure) touches its minimum point. Probably at such times some trace of tissue fluid is actually present, but insufficient to be made apparent by the ordinary use of the differential test.

[Some practical deductions were here drawn, and new remedies suggested by the inquiry were described.]

There is much more work to be done, but meanwhile let me summarise a few provisional conclusions:—

(1) Tissue-lymph is intermittently effused, for example, after the ingestion of food, during exercise, rest after exercise, and during sleep.

(2) The rapid effusion and removal of it in states of rest suggest the existence of a circulation between the blood and the tissue spaces—a circulation independent of the lymphatic circulation.

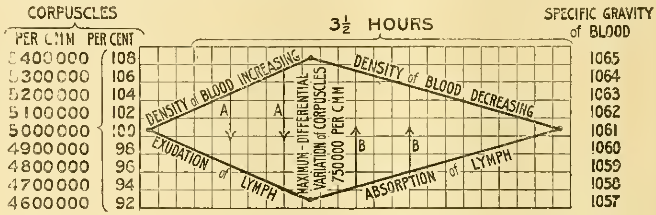

Fig. 5.—Schema showing (AA) exudation of lymph conveying proteids and salts to the tissues and (BB) absorption of tissue fluid containing soluble waste and salts.

(3) The apparent physiological intent of the effusion is reparative, and that of its absorption to aid the removal of tissue waste.

(4) By studying the conditions which increase or decrease lymph effusion, we ought to gain a clearer insight as to how to control derangements of nutrition and metabolism.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Mr. Hubert M. Turnbull, Magdalen College, Oxford, has been elected to a Radcliffe travelling fellowship for three years.

The Rede lecture at Cambridge will be delivered on June 11 by Dr. J. A. Ewing, F.R.S., upon "The Structure of Metals."

Dr. F. G. Donnan, lecturer in chemistry in the Royal College of Science, Dublin, has been elected to the chair of physical chemistry recently founded by Sir John T. Brunner in the University of Liverpool.

The *British Medical Journal* states that the new medical laboratory of the University of Pennsylvania is to be opened on June 30. Exclusive of site and equipment, the building has cost nearly 140,000*l*. It is the first of a group of buildings it is proposed to erect, which when completed will, it is hoped, form the largest system of buildings devoted to the teaching of medicine in the world.

As a general result of the various movements in recent years to establish a centre of veterinary education in Liverpool, it has been arranged, we learn from the *Times*, that Prof. Williams, of the New Veterinary College, Edinburgh, shall transfer his teaching centre to Liverpool and take up the professorship of veterinary medicine and surgery offered by the Institute of Comparative Pathology, and shall act as principal or dean of the veterinary school. Prof. Williams will be placed upon the same footing as professors in the university, and the cost of the professorship has been privately guaranteed for a period of years. In accordance with a scheme drawn up five years ago by

the professors of pathology, physiology, zoology, and botany, veterinary students will be taught in their respective laboratories, and will enjoy, without increase of fees, all the facilities possessed by medical and science students. They will, in addition, have the advantage of the Tropical Medicine, Cancer Research, and Comparative Pathology Schools. This arrangement will provide for the scientific training of the veterinary student upon a scale equal to that of the medical student.

At the concluding meeting of the session 1903–4 of the Architectural Association, Mr. A. E. Munby read a paper on the value of science in an architectural curriculum, in which he urged that science should receive more attention from architectural students. He mentioned some interesting particulars as to the number of hours per week devoted to science by students studying in architectural courses in the great technical schools of the world. To give a few examples, Mr. Munby stated that the architectural student at McGill University devotes 7·9 hours a week to science classes; at University College, London, 6·8; at Glasgow Technical College, 5·3; at the University of Illinois, 4·9; and at the Technischen Hochschule, 2·5. To conclude his paper, Mr. Munby made suggestions as to the subjects of science an architectural student should study at the outset of his career. These should include, he thought, a general experimental course on physics, including laboratory work; a similar course dealing with the elements of inorganic chemistry; and a short course outlining the principles of geology and dealing with the stratigraphical arrangement of rocks and with petrology. The whole of this work might be undertaken by a person of average intelligence at the age of, say, sixteen, and completed in one year with some twelve hours' teaching per week.

In connection with the recent opening of the new buildings, extending the South-Western Polytechnic at Chelsea, the heads of the electrical and mechanical engineering departments have prepared a pamphlet describing the aims and equipments of their respective laboratories. In these laboratories two classes of students receive instruction, viz. those who attend the engineering day courses and those who form the evening classes. The standard of the courses extends far enough to include preparation for the engineering degree of the University of London, and attention is given to the requirements of candidates for the associate membership of the Institution of Civil Engineers. But no particular syllabus is followed, and students are able easily, if necessary, to take other public examinations in engineering. So far as funds have permitted, an attempt has been made to provide in the mechanical engineering laboratory more than one type of some pieces of apparatus, in the belief that the range of experience thus gained by a student is of value, while such a variety enables a number of students to be less thickly distributed over the apparatus. Many of the larger pieces of apparatus have not been specially designed for experimental purposes, but are ordinary standard commercial machines which have been fitted with the necessary measuring appliances by students and the workshop instructor. The electrical engineering laboratories are divided into three principal rooms—the large laboratory where the testing of electrical instruments and the measurement of electrical quantities are carried out; the dynamo room where the experiments and investigations on dynamos and motors are conducted, and the "advanced" laboratory where the standard instruments are kept and used for calibrating the instruments used in experimental work, and where the more advanced alternating and polyphase current experiments are made. In addition to these rooms, there are two rooms fitted up for photometric tests on incandescent and arc lamps respectively. There is also a large wiring shop for instruction in practical wiring and jointing, and two workshops for repairing and making apparatus for the electrical laboratories. There are in all six steam engines specially fitted up for experimental work. Recently, when the electric lighting plant had to be duplicated, advantage was taken of the opportunity for fitting the new engines with measuring appliances, so that experiments could be carried out on them whenever desired. The plant available permits of the setting aside of either of the new engines for experiment, or the unit experimented upon can be made to provide electrical energy for lighting the building (Fig. 1). The pamphlet contains a full description, with illustrations, of all the more important pieces of apparatus in both departments of engineering.

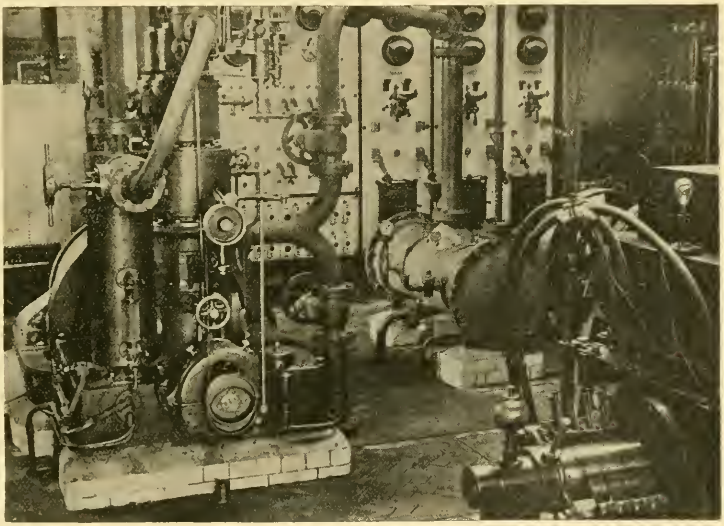

Fig. 1.—Main Lighting Plant of the South-Western Polytechnic.

SOCIETIES AND ACADEMIES.

London.

Royal Society, April 28.—"The Effects of Changes of Temperature on the Modulus of Torsional Rigidity of Metal Wires." By Dr. Frank **Horton**.

An account of some experiments performed at the Cavendish Laboratory with the view of ascertaining as accurately as possible the manner in which the modulus of torsional rigidity varies with the temperature. The metals experimented on were copper, iron, platinum, gold, silver,

aluminium, tin, lead, cadmium, all chemically pure, and also specimens of commercial copper and of steel pianoforte wire. A dynamical method of experimenting was employed, the torsional oscillations of the wire under test being timed by a method of coincidences capable of great exactness. The method of coincidences is usually only applied to the comparison of two nearly equal times, but it is shown to be equally applicable to any two periods, even if they are quite different. Observations were made, in general, at five temperatures, viz. at the temperature of the room, about 10° C., at 35° C., 55° C., 75° C. and 100° C., and also in some cases at 126° C., the higher temperatures being obtained by using the vapours of various liquids boiling under atmospheric pressure. The coefficients of expansion of the wires used (which are required in order to compare observations at different temperatures) were determined by means of the measuring bench in the physical laboratory of the University of Birmingham. The internal viscosities of the wires, and the effect of increased amplitude of vibration, were also investigated. The main observations for the rigidity determinations were all taken at an average amplitude of fourteen minutes.

The following is a summary of the principal results:—

(1) In all the materials examined, with the exception of pure copper and of steel, the modulus of rigidity at one temperature is not constant, but increases as time goes on.

(2) The diminution of the modulus of rigidity per degree rise of temperature between 10° C. and 100° C. is constant for pure copper and for steel, but not for any of the other materials examined.

(3) In general, the effect of heating to a high temperature is to increase the value of the rigidity modulus at lower temperatures.

(4) The internal viscosity of all the metals examined, with the exceptions of soft iron and steel, increases with the temperature. The internal viscosity of soft iron decreases rapidly with rise of temperature, and reaches a minimum value at about 100° C. There is a slight decrease also in the case of steel.

(5) Repeated heating and continued oscillation through small amplitudes decrease the internal friction.

(6) Both the internal friction and the period of torsional vibration increase with the amplitude of oscillation.

(7) Vibration through a large amplitude considerably alters both the logarithmic decrement and period of oscillation at smaller amplitudes.

(8) The internal viscosity of a well annealed wire suspended and left to itself gradually decreases.

"On the Sparking Distance between Electrically Charged Surfaces." By Dr. P. E. **Shaw.**

Recent investigation (1901) on this subject has been made by R. F. Earhart, who used voltages from 1000 to 38, the corresponding distances being from 100 microns to $\frac{1}{4}$ micron. In the present paper the voltages range from 150 to $\frac{1}{8}$, and the distances of discharge from 1 micron to 1/500 micron. The instrument used to measure these small distances is the electric micrometer, which works on the principle of electric touch, and is therefore specially suitable to measurements of this kind.

The relation between voltage and sparking distance is found to be linear, and direct from the origin; hence it is evident that there is no change in dielectric strength in any film or films existing on the surfaces of the solid bodies used at the points of discharge. Since 1 volt or thereabouts is so frequently employed in electric circuits, there is especial interest in knowing the sparking distance for this voltage; it is about 1/100 micron, and unless sufficient pressure is used to squeeze out dust or films until the metal surfaces approach to this distance, no current can pass.

The two surfaces used for discharge are a bead and a plane, generally of polished iridio-platinum. The pressure used is atmospheric. In working with such minute distances care must be taken to exclude extraneous vibrations, and the surfaces must be re-polished after every discharge except when the voltages are less than 10. In every case the discharge is observed by a telephone suitably shunted.

Geological Society, April 27.—Dr. J. E. Marr, F.R.S., president, in the chair.—On a new species of Eoscorpius from the Upper Carboniferous rocks of Lancashire: W. **Baldwin** and W. H. **Sutcliffe.** The specimen described was found in an ironstone-nodule occurring on a fairly well marked horizon, about 135 feet above the Royley Mine (or Arley Mine) coal-seam, at Sparth Bottoms, south-west of Rochdale Town Hall. The nodules occur in a band of blue shale, in which are well preserved remains of *Carbonicola acuta*, ferns, Calamaria, *Prestwichia rotundata*, and *Bellinurus bellulus*. The animal is well represented by both the intaglio and relievo impressions; these, however, only show its dorsal aspect. The specimen is referred to a new species. Dr. Peach is of opinion that the ancient species visited the sea-shore in search of the eggs of invertebrates, and the association of this new scorpion with king-crabs at Sparth Bottoms is in favour of this view.—The genesis of the gold-deposits of Barkerville (British Columbia) and the vicinity: A. J. R. **Atkin.** The gold-bearing area of Cariboo is roughly confined, within a radius of 20 miles of Barkerville, to the band of crystalline rocks known as the Cariboo schists, generally assigned to the Lower Palæozoic group. The veins follow the strike but not the dip of the rocks; the gangue is similar to that associated with the nuggets in the placers. While all the reefs carry gold, none have been found rich enough to account for the placer-gold. The placer-gold has probably been derived from the enriched outcrops of the veins which once existed above water-level. Such enrichment is due to the leaching out of pyrites leaving the less soluble gold in lighter quartz, and to actual enrichment by precipitation. While the enriched zone was being formed, the weathering of the surface kept removing the leached outcrop, and constantly exposing fresh surfaces to atmospheric influences. To the weathering of these outcrops the rich placers are attributed. The denudation of the reefs and the deposition of gold in the gravels appear to have taken place in Tertiary times.

Zoological Society, May 3.—Mr. G. A. Boulenger, F.R.S., vice-president, in the chair.—Mr. Oldfield **Thomas,** F.R.S. read a paper on the osteology and systematic position of the rare Malagasy bat *Myzopoda aurita*.—Mr. F. E. **Beddard,** F.R.S., read a third of a series of papers on the anatomy of the Lacertilia, which dealt with points in the vascular system of chamæleon and other lizards.—A communication was read from Mr. A. D. **Imms** containing notes on the gill-rakers of the ganoid fish Polyodon.—Dr. W. G. **Ridewood** read a paper on the cranial osteology of the fishes of the families Elopidæ and Albulidæ, with remarks on the morphology of the skull in the lower teleostean fishes generally.

Entomological Society, May 4.—Prof. E. B. Poulton, F.R.S., president, in the chair.—Mr. W. J. **Kaye** exhibited a piece of the plant *Eupatorium macrophyllum* from British Guiana, attractive to Lycorea, Melinæa and Mechanitis species of that region, and a remarkable larva-like twig of birch. The resemblance was so complete that even the head, the segments, the appressed legs and the anal claspers appeared to be represented. It had been found on Oxshott Heath while searching for larvæ of *Geometra papilionaria*. He also exhibited on behalf of Mr. C. P. Pickett a pupa of *Rumia crataegata* which had spun up in an empty pupa case of *Pieris brassicae*. The latter was on the roof of a breeding-cage, and the geometrid larva had completely crept inside to spin its cocoon.—Mr. J. E. **Collin** exhibited *Corethra obscuripes*, v. d. Wolf (?=*C. fusca*, Staeg.), a little known species of the genus, and new to the British list, which he had found in some numbers at Newmarket. Mr. G. T. **Porritt** exhibited a living larva of *Agrotis ashworthii*, of which species he had found considerable numbers on one of the mountains of Carnarvonshire during the last week in April.—Commander J. J. **Walker,** R.N., exhibited a gall sent him by Mr. Harold S. Mort, identified by Mr. Froggart as *Brachycelis duplex*, Schrader, and found at Wentworth Falls, Blue Mountains, N.S.W., where it was by no means common.—Mr. G. H. **Verrall** exhibited three specimens from the Hope collection at Oxford of *Neoitamus cothurnatus*, Meig., an Asilid not previously recorded as British. They were taken near Oxford by Mr. W. Holland. He also stated that the Anthrax exhibited at the last meeting on behalf of Mr. R. G. Bradley was *A. circumdata*, Meig., a species recorded before, but not observed for more than fifty years past.—

The **President** exhibited a Longicorn beetle captured near Malvern, Natal, by Mr. C. N. Barker, together with a large Bracon from the same locality, to which, on the wing, it showed a close superficial resemblance.—Mr. H. J. **Turner** exhibited living larvæ and cases of several species of the lepidopterous genus Coleophora, and contributed notes on them.—Dr. A. Jefferis **Turner** communicated a paper entitled "A Classification of the Australian Lymantriadæ."—Dr. F. A. **Dixey** read a paper by Major Neville Manders, R.A.M.C., entitled "Some Breeding Experiments on *Calopsilia pyranthi*, and Notes on the Migration of Butterflies in Ceylon."

Chemical Society, May 5.—Prof. W. A. Tilden, F.R.S., president, in the chair.—The following papers were read:—The slow combustion of ethane: W. A. **Bone** and W. E. **Stockings.** The hydrocarbon is first oxidised to acetaldehyde, the latter then passes into formaldehyde, and this is eventually oxidised to carbon dioxide, carbon monoxide and steam.—The action of radium rays on the halides of the alkali metals, and analogous effects produced by heat: W. **Ackroyd.** The γ-rays from radium bromide produced no colour change with lithium chloride, but with sodium, potassium, rubidium and cæsium chlorides produced yellow, violet, bluish-green and green transitory colorations respectively. These changes are analogous to the thermal effects produced in other substances, and are probably like these purely physical.—The mutarotation of glucose and galactose. Solubility as a means of determining the proportions of dynamic isomerides in equilibrium: T. M. **Lowry.** The author has applied the method already used in the case of β-bromonitrocamphor to these sugars, and finds that the stereoisomerides are approximately equally stable, and are present in about equal proportions in solutions. A study of the substitution products of *ar*-tetrahydro-α-naphthylamine. 4-Bromotetrahydro-α-naphthylamine and *ar*-tetrahydro-α-naphthylamine-4-sulphonic acid: G. T. **Morgan,** Miss F. M. G. **Micklethwait** and H. B. **Winfield.** Studies in the tetrahydronaphthylamine series, part ii., halogen derivatives of *ar*-tetrahydro-β-naphthylamine; part iii., reaction between *ar*-tetrahydro-β-naphthylamine and formaldehyde: C. **Smith.** A description of the derivatives obtained in these reactions.—The resin acids of the Coniferæ, part i., the constitution of abietic acid: T. H. **Easterfield** and G. **Bagley.** A description of the various decomposition products of abietic acid is given; a study of these led the authors to the conclusion that this resin acid is a decahydroretenecarboxylic acid, and they suggest that in retene the methyl and *iso*propyl groups occupy a *meta* position relatively to each other.—Additive products of benzylideneaniline with ethyl acetoacetate and ethyl methylacetoacetate: F. E. **Francis** and Miss M. **Taylor.** These additive products are shown to exist in one form only.—Studies on ethyl carboxyglutarate, part i., action of acids on ethyl sodiocarboxyglutarate: O. **Silberrad** and T. H. **Easterfield.**—Studies on optically active carbimides, part i.: A. **Neville** and R. H. **Pickard.**—The comparison of the rotation values of methyl, ethyl and *n*-propyl tartrates at different temperatures: T. H. **Patterson.** It is shown that a connection between the rotation values of these esters may be traced when the comparison is made at corresponding temperatures.—Note on the action of hydrogen sulphide on formaldehyde and acetaldehyde solutions: J. **Drugman** and W. E. **Stockings.** A description of a number of complex thio-derivatives obtained in these reactions.—The viscosity of liquid mixtures: A. E. **Dunstan.** The effects of the chemical affinity, molecular aggregation, and to some extent of the chemical constitution of the constituents on the viscosities of liquid mixtures are discussed.—The conversion of *iso*propyl alcohol into *iso*propyl ether by sulphuric acid: F. **Southerden.** In opposition to the experience of previous investigators, the author has obtained a small yield of *iso*propyl ether by this reaction.

Royal Astronomical Society, May 13.—Prof. H. H. Turner, F.R.S., president, in the chair.—The secretary gave an account of a paper by Dr. **Downing** on the definitive places of the standard stars for the northern zones of the Astronomische Gesellschaft, and also of two papers by Mr. **Cowell** on the moon's errors in longitude.—A brief account was given of a second series of double star measures by the Rev. T. E. **Espin.**—The **Astronomer Royal** read a paper on the new Greenwich micrometer for measurement of photographs of Eros. As the measures were required for determination of the solar parallax, a greater degree of accuracy was necessary than for the Astrographic Chart. A new instrument was therefore constructed, on the lines of Mr. Hinks's Cambridge measuring machine, and the results obtained with it were extremely satisfactory, the measures being remarkably accordant. The micrometer was described and illustrated by photographs shown on the screen.—Mr. **Franklin-Adams** read a paper on his photographic chart of the heavens, to Argelander's scale $1^{\circ} = 20$ mm. After much preliminary work and an extended series of experiments, a 10-inch photographic lens was made by Messrs. Cooke and Sons from designs by Mr. Dennis Taylor, and this was provided with a specially constructed mount of the English form, with two guiding telescopes instead of one, and various other improvements. The instrument was taken to the Cape in June, 1903, and by the kindness of Sir D. Gill was erected in the grounds of the observatory. The work of photographing the southern heavens on 115 plates, each 15 inches square, with two hours' exposure, was practically completed, as well as a set with triple exposures, and another taken with a 6-inch lens. The star images were very good, even towards the edge of the plates, the lenses having proved extremely satisfactory, and the driving arrangements specially good. Photographs of the instrument and specimens of the plates were shown on the screen.—Mr. **Bellamy** gave an account of his paper on a new cluster in Cygnus, and other papers were taken as read.

PARIS.

Academy of Sciences, May 16.—M. Mascart in the chair.—The president announced to the Academy the loss by death of M. Marey, member of the section of medicine and surgery, and of M. Sarrau, member of the section of mechanics. The death of Prof. Williamson, correspondant for the section of chemistry, was also announced.—The cooling power of a feebly conducting fluid current on a body limited in every direction: J. **Boussinesq.**—On the electrolysis of calcium chloride: H. **Moissan.** A reply to some criticisms of M. Bullier with reference to a claim for priority.—The effect of small oscillations of temperature on a system affected by hysteresis and viscosity: P. **Duhem.** Small oscillations of external action and of temperature have no appreciable influence on the transformation of a system when the coefficient of viscosity of this system is large with respect to the amplitude of the oscillations.—Researches relative to the resistance of the air made by means of a new apparatus called the dynamometric balance: Ch. **Renard.** Two different forms of apparatus are described, the simple balance, which permits of the calibration of wind vanes for dynamometers, and the double balance, specially employed in the study of helices. Three illustrations are given.—On the function of the *n*-rays in causing changes of visibility in feebly illuminated surfaces: Jean **Becquerel.** The conclusion is drawn from the experiments described that the change in the distinctness and luminosity of feebly lighted surfaces submitted to the action of the *n*-rays is probably to be attributed, at least in great part, to a variation in the sensitiveness of the vision arising from the *n*-rays directed on the surfaces, and not to an appreciable variation in the light emitted.—The explanation of some colour phenomena shown by a tube containing rarefied gas: H. **Pellat.**—On the microscopic state of the poles and the discharge spectra: B. **Eginitis.**—On the density of aqueous saline solutions considered as an additive property of the ions, and on the existence of some hydrated ions: P. **Vaillant.**—A new method for the exact determination of the molecular weights of the permanent gases; the atomic weights of carbon, hydrogen and nitrogen: Ph. A. **Guye.** The author, with M. Friderich, has previously established that the van der Waals equation leads to the relation $V_m(1+a)(1-b) = R$, where V_m represents a gram-molecule at 0° C. and under the pressure of one atmosphere, a and b the two constants of the equation of fluids with respect to unit volume, and R the gas constant. In the present paper R is replaced by $R - mT_c$. By applying this relation to the experimental results of Leduc, Morley and Rayleigh, the values of the atomic weights of hydrogen,

carbon and nitrogen are determined. For the last named element the mean value is 14·004, as against the figure of 14·057 of Stas.—On the preparation and properties of hypophosphorous acid: C. **Marie.** Two methods are given, starting from the barium and sodium salts respectively, both of which yield a pure crystalline acid of melting point 26·5. The decomposition by heat was also studied, and the equation ordinarily accepted for this change shown to be erroneous.—On a crystallised chromous tartrate: G. **Bauge.**—Colouring matters derived from triphenylmethane: Charles **Lauth.**—The preparation of the α-β-ketonic esters: L. **Bouveault** and A. **Wahl.** A study of the reaction between nitrogen peroxide and ethyl isonitrosoacetoacetate.—The action of phosphorus trichloride and some primary cyclic amines at the boiling point; the reduction of the chloride with the formation of phosphorus: P. **Lemoult.**—On some new polymers of formaldehyde: A. **Seyewetz** and M. **Gibello.**—The action of paraformaldehyde upon the sesquiterpenes: P. **Genvresse.** Carophyllene, clovene and cadinene all combine with formaldehyde.—Researches on the mechanism of the circulation of aromatic compounds in plants: Eug. **Charabot** and G. **Laloue.**—The action of heat and acidity on amylase: P. **Petit.**—The organisation and morphogeny of the Ætheridæ: R. **Anthony.**—Observations on Gymnoascus and Aspergillus: P. A. **Dangeard.**—Some remarks on the ancient Cryptogams and fossil plant soils: B. **Renault.**—Study of the spinal cord by means of the *n*-rays: André **Broca** and A. **Zimmern.** From their preliminary observations the authors conclude that the examination of the spinal cord by means of the *n*-rays allows of the demonstration on the living man of the existence of medullary centres, and even to gain some idea of their degree of activity.—On the presence of geminal nuclei in the cells of certain tissues of the guinea pig: Maurice **Pacaut.**—Light, food, and chlorophyll as modifying factors in the development of Amphibia: Georges **Bohn.**—On a mode of bacterial extraction of spring and river water by means of fine sand: P. **Miguel** and H. **Mouchet.**

THURSDAY, JUNE 2, 1904.

SIR WILLIAM FLOWER.

Sir William Henry Flower, K.C.B., &c.; a Personal Memoir. By C. J. Cornish. Pp. xi+274; illustrated. (London: Macmillan and Co., Ltd., 1904.) Price 8s. 6d. net.

THAT the life of a man of the social and scientific position of the late director of the natural history branch of the British Museum should be written, and written, moreover, by a master of popular literature, will, we think, be admitted on all hands, and in tendering a hearty welcome to this record of a distinguished career and a fine character, we trust we shall be expressing the views of no inconsiderable section of the public, and of all our readers. Mr. Cornish, whose name needs no introduction of ours to the reading public, has been fortunate in securing the cooperation of several members of the late Sir William's family in the compilation of the memoir before us, so that all the details with regard to early life and family history may be accepted as thoroughly authentic. The first two chapters, dealing with the period ending with the return from the Crimea, are, indeed, written by Mr. Victor Flower, Sir William's youngest son, while the final chapter of the biography, describing the closing scenes, is from the pen of his widow, Lady Flower. Nor is this by any means all in the way of contributions by members of the family to the biography, for the eldest daughter of Sir William, Mrs. Shann, takes the public into her confidence with regard to family life in the well known house adjacent to the Museum of the Royal College of Surgeons, while another daughter, Mrs. Biddulph, communicates a note on the summer holidays of the Flower family in early days. No critic can therefore complain of any lack of breadth in the lines upon which the biography has been drawn up; we have, indeed, not only the life-history of the central figure, but a large amount of information with regard to the family generally.

The memoir, as the author says in his preface, is essentially a personal one, and does not in any way claim to give an account of Sir William's scientific work, which must remain for a future biographer.

Although the biography of a scientific man in which there is no detailed reference to, or criticism of, the work from which he gained his reputation reminds us of the well known saying in regard to the play of "Hamlet," yet, if we may judge from what little he has attempted in this line, Mr. Cornish has been decidedly well advised in confining himself in the main to the personal aspect of his subject. When, for instance, he strays even such a short distance away from this track as to compile a list of Sir William's scientific papers, he displays a lamentable carelessness and a lack of knowledge of both the principles of bibliography and of zoological nomenclature. The want of accuracy in matters of this nature is indeed displayed even on the title-page of his memoir, where we find Sir William described as president of the *Royal* Zoological Society.

To justify our assertion as to the want of care displayed in the compilation of the list of scientific papers and books given in one of the appendices,[1] we need only refer, in the first place, to the following "misprints," as we suppose they must be euphemistically termed. On p. 252 we have, for instance, *Hylobatus* for *Hylobates*, *syndactilis* for *syndactylus*, and *javenicus* for *javanicus*. On the following page, and elsewhere, we find *Physalius* for *Physalus*, on p. 254 *geoffrensis* for *geoffroyensis*, and on p. 256 *Helitherium* for *Halitherium* and *arnuschi* for *arnuxi*. Nor are such errors confined to the appendix, for in the text (which is wholly the author's) we find on p. 121 Etteridge for Etheridge, and on p. 175 *Hyperodon* for *Hyperöodon*. In the case of the bibliography, at any rate, such errors (at which no one would have been more annoyed than Flower, who was the very spirit of accuracy in such matters) might have been easily detected by checking the list with the Royal Society's "Catalogue of Scientific Papers."

Nor is this all, for we find want of uniformity in regard to the references to the serials in which the papers originally appeared. For instance, we have on p. 257 *Journ. Anth. Inst.* and on p. 258 *Anthropol. Inst. Journ.*, while on the latter page we find *Zool. Soc. Proc.* as the equivalent of *Zool. Soc. Proc. London* on p. 260. Again, we should much like to know the meaning, so far as the Roman numerals are concerned, of the following entries on the page last mentioned, viz. "Zool. Soc. Proc. London, 1884, cxi. p. 417," and "Zool. Soc. Proc. London, 1884, xi. p. 206."

Reverting to the book itself, we find the fourth and fifth chapters devoted to the period during which Flower was officially connected with the Museum of the Royal College of Surgeons. Here the author records the energetic manner in which Flower set himself to work to render the museum more useful to students, and the inventions he devised for the better display or more convenient handling of the specimens exhibited. Family life during this period forms the subject of chapter vi., while in the following chapter we are introduced to some of Sir William's personal friends, among whom were Dean Stanley, Prof. Huxley, and the late Duke of Argyll. Chapters ix. to xiii. treat of the second portion of Sir William's official career, during which he was head of the museum in the Cromwell Road. Here, in the main, the author records very fairly the changes and improvements introduced gradually and tactfully during Flower's administration, dwelling especially on the installation of the "index museum" and the other contents of the central hall, and also directing attention to the better manner of displaying specimens introduced under the new *régime*. We fail, however, to understand the meaning of the sentence on p. 149, in which it is recorded that

"In 1898 the rearrangements of the mammals on Flower's system were nearly completed for the classes Chiroptera (bats), Edentata, and Primates."

As a matter of fact, the provisional arrangement of all the orders (not classes) had been by that time com-

[1] The list is stated to have been compiled by Mr. Victor Flower, but the author must be held responsible for its inaccuracies.

pleted (so far as anything in a museum can be said to be complete), while the Edentata, which was one of the first groups taken in hand, had been arranged at least a couple of years previously.

Limitations of space forbid fuller notice, and we may conclude by mentioning that while special chapters are devoted to his favourite subjects, anthropology and cetaceans, the three final chapters deal with the later and closing scenes of Sir William's life. Of four excellent portraits, those taken in his later years serve to remind old friends of Flower's striking personality. Bearing in mind the limitations already mentioned, the author is decidedly to be congratulated on the attractive manner in which he has laid before the public the main features of a very interesting and highly successful scientific career. R. L.

THE IDENTIFICATION OF ORGANIC COMPOUNDS.

A Method for the Identification of Pure Organic Compounds. Vol. i. By S. P. Mulliken, Ph.D. Pp. xii+364. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1904.) Price 21s. net.

THIS is the first of a series of volumes which are intended to facilitate the identification of organic substances. The scheme commonly, though not invariably, adopted by organic chemists in this connection is to determine the molecular formula of the compound under investigation, and then to refer to Richter's "Lexicon," in which all known organic compounds are tabulated according to their molecular formulæ. Further agreement is established by a comparison of physical and chemical properties. The author considers that the difficult technique of conducting an ultimate organic analysis, upon which the above system mainly depends, "is fully mastered only by long practice," and that there is a shorter cut to the same result. This short cut consists in finding, in the first instance, to what class of compounds—hydrocarbon, alcohol, aldehyde, acid, &c.—the substance belongs, and, when this has been done, in determining such simple physical characters as melting-point, boiling-point, specific gravity, colour, smell, &c., which will lead to its identification. It is therefore necessary for purposes of reference that all the known organic compounds should be grouped into separate classes. This is what the author has done. In each class the individual members are arranged in the order of increasing boiling-point or melting-point. For example, let us suppose that the substance, the identity of which is required, proves to be an acid. All the known organic acids are divided into tables of liquid and solid acids, and these again into categories, which are either soluble or insoluble in water. Suppose that the acid under investigation is a liquid which is soluble in water. Having turned to the table containing the liquid acids soluble in water, an examination of the first column of boiling points will lead, perhaps, to the discovery of one corresponding to the unknown acid. Under this compound a series of characteristic reactions are described which will enable the investigator to fix the identity of his compound by means of a few simple tests.

There is very little that is new in the above method. It is one which is adopted, consciously or otherwise, by the majority of chemists, whether they possess the skill requisite to conduct an ultimate organic analysis or not. That carefully elaborated methods are at present in use for determining the constitution of a substance by chemical tests is clearly shown by the existence of such a volume as Hans Meyer's, which has been translated into English, and has already reached a second edition.

In point of fact, when a substance has been obtained in a state of purity, its identification is as a rule not a serious undertaking. The character of the substance from which it is derived will usually furnish a clue to its nature, and a few characteristic tests will soon set the matter at rest. If the identification of a compound is a crucial matter, few chemists would rest content with anything less than a direct comparison of the product with the known substance, for melting- and boiling-points are apt to vary a little with the apparatus and form of thermometer employed, and colour reactions do not always produce quite the same tint unless the conditions of the experiment are the same.

It is the separation of a compound from a mixture and its purification which make the greatest demands on the skill and experience of a chemist. Compared with this, an ultimate organic analysis and the characterisation of a compound by chemical tests offer little difficulty.

There is no intention to disparage the labour which has been expended on this work. The careful revision of the reactions of many of the substances found in the tables would entitle the book to grateful recognition, in addition to which there is much useful and practical information on the method of applying the different reactions which every organic chemist will appreciate. It would be incorrect, moreover, to state that the tables will not serve the object for which they have been compiled. The question is only whether the object is worth the labour which it entails, seeing that most of the information may be derived indirectly from other sources.

The biological system of classification of substances into orders, genera and species cannot be commended. It is unnecessary and undesirable. There is no analogy in the application of these terms in the two sciences, and their use may be misleading. Chemical nomenclature still suffers in this country from such a false analogy, when *radicle* was adopted in place of *radical*. J. B. C.

THE MIND OF THE CHILD.

Educational Psychology. By Edward Thorndike, Adjunct Professor of Genetic Psychology in Teachers' College, Columbia University. Pp. vii + 177. (New York: Lemcke and Büchner, 1903.)

THIS volume embodies the results of investigations in which Prof. Thorndike has interested himself and his pupils for some time past, applying the methods

of experimental psychology to educational problems. Seeing that it is the first serious treatise on the subject which has yet appeared, such a pioneer work naturally deserves warm welcome and temperate criticism, even though there be important points of detail, both in the methods employed and in the conclusions drawn, which can hardly be accepted without reservation. As Prof. Thorndike ably points out in the last five pages of his book, there are numerous problems and experiments described by him which any trained teacher "can attack with a fair promise of success." His obvious aim in publishing this work at the present primitive stage of genetic psychology is to encourage a greater number of workers in the field of research with which he has so closely identified himself in the United States. For this reason, doubtless, he has omitted all consideration of the comparative data already available in other countries than his own.

The first two chapters are devoted to the methods of measurement and to the statistical distribution of mental traits within the community. The view is upheld that "the distribution of any mental trait in a homogeneous species undisturbed by selection is that given by the probability integral." It is to be regretted that the author has not devoted more space to statistical methods. Such sentences as the following, on p. 20, are surely unwise:—"The mathematical formulæ by which this is done need not concern us here." "Here again the mathematical formulæ are best omitted. The reader may take it on trust that such a transposition as the following is correct."

The third chapter concerns the correlation between different mental abilities in the same individual. An endeavour is made to define the certainty with which any scholar who is especially proficient in one subject of study will surpass or fail to reach the average in other subjects. It is experimentally shown that the phrase "ability in arithmetic" is "but an abstract name for a number of partially independent abilities."

The remaining chapters are concerned with experimental work upon the connection of mental traits with sex and age, upon the relation between mental and physical traits, and upon the influence of heredity and environment. Within the limits of this notice it is impossible even to summarise the many highly interesting results of the experiments of the author and his countrymen. As the author observes,

"The science of education when it developes will like other sciences rest upon direct observations of and experiments on the influence of educational institutions and methods made and reported with quantitative precision. . . . It is the vice or the misfortune of thinkers about education to have chosen the methods of philosophy or of popular thought instead of those of science. We ruminate over the ideas of Pestalozzi or Herbart or Froebel as if writing a book a hundred years ago proved a man inspired. . . . We are like chemists who should quarrel over the views of Paracelsus or Arnauld of Villeneuve. . . . In education everything is said but nothing proved" (p. 164).

This book is a worthy and welcome attempt to apply exact method to educational problems, although it leaves some little to be desired in style and general appearance. CHARLES S. MYERS.

OUR BOOK SHELF.

Précis d'Électricité Médicale, Technique Électrophysiologie, Électrodiagnostic Électrothérapie, Radiologie, Photothérapie. By Prof. E. Castex. Pp. vii + 672; 208 figures. (Paris: F. R. de Rudeval, 1903.)

THE object of the author has been to furnish the medical student with a work which will be useful to him in the present state of electrical knowledge, but the author hopes that it will also not be without value to medical men who are devoting themselves to the special study of electrotherapeutics, and likewise to practitioners who have not had such opportunities.

The work is divided into five different sections, including technique, electrophysiology, electrodiagnosis, electrotherapy, and lastly the study of X- and other rays.

The author has been very successful in the arrangement of his matter, and the physical aspect of the question has not been neglected, judging, of course, from the medical point of view. The various currents employed in medicine, continuous, interrupted, sinusoidal, high-frequency, and static, have all been practically and efficiently explained. The second and third chapters, dealing with electrophysiology and diagnosis, will be found particularly useful to those who desire a practical and not too exhaustive guide. The application of electricity to the diseases of the different organs is described in concise and practical terms, a fact which will be useful to physicians who have not had the advantages of modern training at one of the electric departments which now form a part of most large hospitals. The last chapter, which is devoted to X-rays, occupies something like 120 pages, and cannot, of course, be expected to compete with the larger treatises, such as Bouchard's, recently published. But again Prof. Castex has shown his practical tendency by giving under each heading a short and very useful guide to the interpretation of photographic as well as radioscopic diagnosis, and radiotherapy itself, although briefly treated, has not been forgotten.

The work contains about 208 illustrations, well chosen to assist the student in understanding the theories, instruments, and clinical charts.

A careful perusal of the work will show that it has been written by one who understands his subject and the needs of the student and practitioner. It is concise, thoroughly practical, and just such a guide as should appeal to those for whom the author has written the work. J. M.

Radium and All About It. By S. Bottone. Pp. 96; with four figures and four full-page plates. (London: Whittaker and Co., 1904.) Price 1s. net.

THE appearance of a popular shilling volume dealing with the properties of the salts of radium and the theory of radio-activity may be regarded as an indication of the wide interest that has been aroused by the discovery and investigation of the radio-active elements. There is much to be said in favour of the production of a book that shall satisfy the curiosity of those whose interest has been aroused but whose knowledge of chemistry and physics is insufficient to enable them to follow the developments of the subject in the technical journals. In spite of its rainbow-tinted cover and its somewhat boastful title, the present volume gives a substantially accurate account of the most important phenomena. It contains liberal quotations from the chief workers in the subject, though these are taken chiefly from articles that have appeared in the non-technical journals and reviews. The author appears to have derived his information almost entirely

from English sources, and to have devoted more attention to popular expositions than to the original literature of the subject. The volume is consequently not free from the faults that are almost inseparable from a compilation of this kind, and the arrangement of the matter is in places somewhat confusing. But the author has made a sober and honest attempt to give a simple explanation of a very complex subject, and has attained a fair measure of success. The figures are clearly and simply drawn, and the full-page plates, which include reproductions of the spectra of radium, calcium and helium, and of Sir William Huggins's two series of spectra, are valuable features of the book.

Second Stage Botany. By J. M. Lowson. Pp. viii+452. (London: W. B. Clive, 1904.) Price 3s. 6d.

THE syllabus of the second stage examination in botany of the Board of Education has been judiciously framed on broad lines, and those students generally shape best who possess a reasonable knowledge of the structure and activities of plants and apply that knowledge in their answers. In the preparation of students for this examination the primary object should be to emphasise leading principles, and further to stimulate reflection by making the student observe many facts for himself. Instead of this one finds in the book under notice the usual attempt to supply directly all the information required to answer the manifold questions which are possible, and important facts are lost in the mass of detail. In the latter part of chapter ii., which deals with tissues, the most essential fact is the importance of the vascular tissues as continuous conductive strands, but this is relegated to one of the final sections, which is reached after wading through descriptions of meristems, stereid bundles, sclerotic cells, &c. The chapter on the leaf bristles with terms, including the "incubus" of phyllotaxis, but any suggestions as to the reasons for the variety of form are considered unnecessary. Another defect in the book is the inclusion of antiquated terms and ideas, of which the most noticeable, because it is accompanied by a diagram (Fig. 105), is the existence of centrospheres in Phanerogams. The description of "double-fertilisation" is peculiar; on p. 199 it is stated that the generative cells pass down into the pollen tube, and one cell fuses with the oosphere; "the fate of the other generative cell is described on p. 304." One is tempted to find a correlation between this method of incorporating the result of recent research and the statement which appears in the introduction, that a large portion of this work has already appeared in the author's "Text-book of Botany."

Les Frontières de la Maladie. Maladies latentes et Maladies atteruées. By Dr. J. Héricourt. Pp. xi+285. (Paris: Ernest Flammarion, 1904.) Price 3.50 francs.

ALTHOUGH in well marked cases health and sickness are distinct and opposite conditions, in a large number of instances the boundary between the two is indefinite, the one passing insensibly into the other, and it is with this borderland that the author of the work under review deals. Commencing with dyspepsia, he shows how this may pass on into more grave conditions, and by natural stages finally comes to consider the mild types of such infective diseases as scarlatina, enteric fever, and diphtheria, which in their mildest forms cause little disturbance, and may pass unnoticed and undiagnosed.

Among others, an interesting chapter is devoted to a consideration of how epidemics of disease spontaneously die out. As treating of a little studied branch of medicine, the book is suggestive and to be recommended. R. T. HEWLETT.

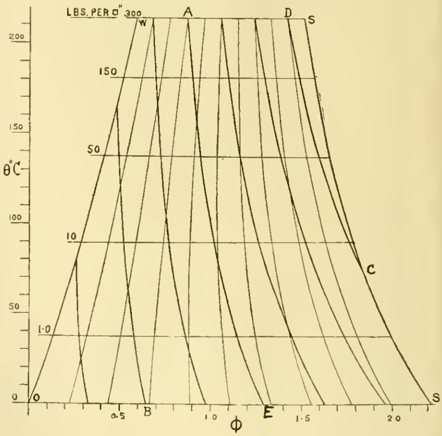
$\theta\phi$ Lines of Total Heat.

I THINK that $\theta\phi$ diagram curves showing constant total heat, although often drawn by students, have never yet been published, and I venture to ask you to publish a set made more carefully than usual by one of my students, Mr. A. W. Steed. Total heat is intrinsic energy $+ pv$, so that for steam it is what Regnault called his total heat. In the figure I have indicated the pressure, but of course the ordinate is proportional to temperature and the abscissa is entropy. Along OW the stuff is all water. Along SS the stuff is all saturated steam. The thin lines, like AB, show the stuff maintaining the same fractional dryness; for example, along AB the stuff is 0·3 of steam, 0·7 of water. Along the thicker lines, like AE, the stuff has constant total heat.

Many people have the notion that when steam is throttled it is very greatly dried. Of course the drying is greater if

LINES OF CONSTANT TOTAL HEAT "H"



the place of throttling is well protected from loss of heat by a non-conducting covering, and in this case total heat remains constant. Now if the line DC is looked at, it will be seen that steam which is 90 per cent. dry at 300 lb. pressure, if throttled to 150 lb. pressure is about 93 per cent. dry, and if throttled to 50 lb. pressure is about $95\frac{1}{2}$ per cent. dry. Thus the drying effect is not very great.

The effect is evidently more marked with very wet steam. Thus, looking at AE, steam 30 per cent. dry at 300 lb. pressure becomes 42 per cent. dry if throttled to 50 lb.

The lines show at once how much steam at any pressure will result on the Halpin system of storage from each pound of stored hot water. Thus imagine a total heat line from the point W in the figure. A pound of water stored at 300 lb. pressure and reduced to 150 lb. pressure will generate about 0·07 lb. of steam.

I need not mention the other important applications of this diagram. To the right of SS, in the superheated part, lines of constant total heat are horizontal, being lines of constant temperature. JOHN PERRY.

Royal College of Science, South Kensington, S.W.

The Nature of the α Rays emitted by Radio-active Substances.

THE α rays emitted by radium and other radio-active substances have been shown by Rutherford ("Radio-activity," pp. 115–141) to consist of positively charged particles for which $e/m = 6 \times 10^3$. They are rapidly absorbed by gases and solids, the absorption coefficient being approximately proportional to the density of the absorbing medium. The value of the absorption coefficient in air divided by the density varies between 350 and 1300 for different types of α rays. The velocity of these rays is about 1/10th to 1/20th that of light.

It is interesting to compare the properties of these rays with those of kathode rays moving with about the same velocity; e/m for such rays is about 10^7, and the value of their absorption coefficient in air at 1 mm. pressure is 0·85 (Lenard, *Ann. der Phys.*, Bd. 12, p. 714, 1903) when the velocity is 1/10th that of light and 3·9 when it is 1/20th.

The absorption coefficient for these rays is also proportional approximately to the density of the absorbing medium. Dividing 0·85 by the density of air at 1 mm. pressure we get 540,000, and in the same way 3·9 gives 2,500,000. The corresponding numbers for the α rays are about 350 and 1300. Thus we see that the α rays are nearly 2000 times as penetrating as kathode rays moving with the same velocity.

Assuming that $-e$ for the kathode rays is equal to e for the α rays, we have for the ratio of their masses $10^7/6 \times 10^3 = 1700$. It thus appears that the penetrating power of the α rays is to that of kathode rays, moving with the same velocity, approximately as the mass of the α rays is to the mass of the kathode rays. We may conclude from this that an α particle loses as much energy in colliding with an atom as a kathode-ray particle or corpuscle. If we regard the α particles as being of atomic dimensions (that is, as having a radius about 10^{-8} cm.), while an electron or corpuscle only has a radius of about 10^{-13} cm., it is very difficult to understand this result. On the view that all atoms are assemblies of electrons, the fact that the absorption of kathode rays depends only on the density of the absorbing medium is regarded as indicating that the electrons penetrate the atoms and are absorbed by colliding with the electrons which compose the atoms. Since α particles lose the same amount of energy as electrons in penetrating matter, it seems probable that they also penetrate the atoms and lose energy by colliding with the electrons in exactly the same way. If this view is taken, it becomes difficult to regard an α particle as of atomic dimensions, and we may look upon it as a positive electron exactly similar in character to an ordinary negative electron. The mass (m) of an electron is now regarded as being purely electromagnetic in character, and is given by the formula $m = 2e^2/3a$, where a is its radius and e its charge. For a negative electron this gives $a = 10^{-13}$ cm. Regarding an α particle as a positive electron, we get in the same way for its radius about $\frac{1}{2} \times 10^{-16}$ cm. On this view, therefore, the α particles are enormously smaller than the negative electrons.

The properties and modes of occurrence of the α particles are in agreement with the view that they are really positive electrons. For example, they are produced like kathode rays in electric discharges at low pressures (being then known as canalstrahlen), and have very similar properties to kathode rays. The writer therefore suggests the view that α particles may be positive electrons having a radius about 2000 times smaller than negative electrons.

Trinity College, Cambridge. HAROLD A. WILSON.

A Suggested Explanation of Radio-activity.

I AM venturing, in the present note, to add another to the already large number of suggestions as to the meaning of the phenomenon of radio-activity.

It seems to be well established that the apparent instability of the atoms of radio-active substances is not to any great extent dependent on the temperature of the mass; the instability, therefore, is not the outcome of intermolecular collisions. Neither does it seem to arise from an excess of the internal energy of the molecule. For the internal agitation of the molecule, so far as is known, shows itself in the emission of light, and this is associated with high mass-temperature. There is, of course, the possibility, suggested by Prof. J. J. Thomson, that there are internal degrees of freedom not represented in the spectrum of the gas, and that it is the energy of these which forms the starting point of the radio-active process. On the other hand, it is possible that the atomic instability, not being the result of the agitation of the molecules or of the component material parts (ions or corpuscles) of which the molecules are composed, must be traced to the agitation of the ultimate constituents of these ions or corpuscles. If, for instance, we take a definite mechanical illustration, and imagine our universe constructed on the model suggested by Prof. Osborne Reynolds, the source of instability must be looked for in the agitation of the "grains" of which he supposes the ether to be constituted. The velocities of these grains follow Maxwell's law of distribution, so that very high velocities, although rare, are not impossible. It is at least thinkable that a grain moving with exceptionally high velocity may succeed in breaking down the normal piling in its immediate neighbourhood when this is possible (*i.e.*, probably, when in the immediate proximity of matter), and may therefore effect a rearrangement of the adjacent ether structure. A process of this kind would be independent of the mass-temperature; it would, so to speak, depend solely on the ether temperature, which is supposed, on Prof. Reynolds's hypothesis, to be constant throughout space. It seems probable that the rearrangement would consist of the combination and mutual annihilation of two ether strains of opposite kinds, *i.e.* in the coalescence of a positive and negative ion, and would therefore result in the disappearance of a certain amount of mass. There would, therefore, be conservation neither of mass nor of material energy; the process of radio-activity would consist in an increase of material energy at the expense of the destruction of a certain amount of matter.

Apart, however, from this special mechanical model, it seems probable, on grounds of general dynamics, that the ether does not transmit waves in a perfectly unaltered form, and that there is therefore a continual degradation of the energy of regular waves into an energy of random agitation of the ultimate ether structure. This agitation would afford a sufficient cause for the beginnings of the process which results in the breaking up of the atom. Naturally this agitation would have the best chance of effecting a rearrangement when the strain is greatest, and therefore when the ions are most closely packed together. A larger energy of agitation would be necessary when the ions were less closely packed. We should, therefore, expect all matter to be radio-active to some extent, but should expect the greatest amount of radio-activity to be shown by the heavier atoms.

If the instability results from a rearrangement of an ether structure, and not solely of a material structure, we should, *a priori*, on general grounds of physical dimensions, expect the velocity of the ejection to be comparable with the velocity of waves in the ether, this being the only unit appropriate to the measurement of processes depending on the physical constants of the ether. [Just as, for instance, the velocity of a gas streaming into a vacuum might, *a priori*, be expected to be comparable with the velocity of sound in the gas.] The suggested cause of instability is therefore in agreement with the observed velocity of the α particles. J. H. JEANS.

The First Record of Glacial Action in Tasmania.

IN a recent paper on the Glacial geology of Tasmania (*Quart. Journ.* Geol. Soc., vol. lx. p. 38), I referred to Gould's recognition of Glacial action in Tasmania as not having been directly published. This view I accepted on the strength of the statement by Mr. R. M. Johnston ("The Glacial Epoch of Australasia," *Proc.* Roy. Soc. Tasmania, vol. iv., 1893, 1894, pp. 92–3), than whom no one knows better the geological literature of Tasmania, that it was "through verbal communication to a personal friend of my

own, and one of his (*i.e.* Gould's) early associates, that I first, about 20 years ago, became aware of his discovery of many evidences of glaciation in Tasmania."

I have recently found a Parliamentary Paper, issued in 1860, in which Gould describes his recognition of Glacial action in some of the high valleys of central Tasmania. The passage is as follows ("A Report of the Exploration of the Western Country by Mr. Gould," Parl. Pap., Tasmania, 1860, No. 6):—

"In the Cuvier Valley I was struck, both in going and in returning, by the similarity to the terminal moraine of a glacier presented by an enormous accumulation of boulders which chokes the lower end of the valley, and, somewhat like a dam, extends completely across it, with the exception of the point where it is broken through by the river."

I am glad, therefore, to be able to give to Gould the credit of having published the discovery, which in my paper I could only quote as a verbal tradition.

The Cuvier Valley is one day's journey west of Lake St. Clair. A hut, five miles due west of the top of Mount Arrowsmith, occurs in it. J. W. Gregory.

The University, Melbourne, Victoria, April 25.

The Origin of the Horse.

In your issue of May 19 (p. 53) Prof. T. D. A. Cockerell refers to *Equus caballus celticus*, Ewart, as "still surviving in the pure state in Iceland." Prof. Ewart, in his paper on "The Multiple Origin of Horses and Ponies," says that "the few pure specimens of the Celtic pony survive" in the north of Iceland. I take it that Prof. Ewart does not mean that the northern Icelandic breed of ponies is a pure one, but only that certain individuals of this breed exhibit the "Celtic" characters in a very marked degree. In a recent paper (*Proc.* Camb. Phil. Soc., vol. xii., part iv.) Mr. F. H. A. Marshall and I have brought forward both historical and zoological evidence for the mixed origin of the Icelandic pony. It is perhaps worth noting that the people of north Iceland still claim a social superiority over those of the south as being descended chiefly from the second body of colonists which reached the island. In considering the origin of different breeds of the domestic animals ethnological considerations are often important, and, conversely, the examination of local breeds may sometimes throw light on ethnological problems. For example, in the Malay Peninsula the breed of dogs owned by the majority of the jungle tribes usually classed as Sakais differs from that of the Malay pariah, which has recently been adopted in some cases by Semang tribes and also by those Sakais who live in close intercourse with the Malays. The pariah seems likely to oust the Sakai dog completely, and I am not aware that any zoologist has yet made a detailed examination of the latter, which shows certain resemblances to the local race of *Cyon rutilans*.

Of course, investigations into the ethnological distribution of animals must be made with the very greatest care, for not only may one breed oust or swamp another, but the characters of a single individual may prove so dominant that they may prevail in a great number of cross-bred descendants, and so change the character of a breed in a very short time. This has recently happened in the Færöe Isles. As we know from the statements of Landt ("Description of the Faroe Islands," 1798), there were at least two distinct breeds of dogs in these islands at the end of the eighteenth century, one resembling the modern Danish hound, but smaller; the other a short-legged, rough-haired terrier. The two breeds can still be traced on some of the islands, notably on Naalsoe; but in the neighbourhood of Thorshavn, the capital, great alteration has taken place quite recently. Some ten or twelve years ago a Danish governor introduced a well-bred dachshund dog, which inter-bred with the native bitches. In 1903 I could hardly find a single dog in the town which did not show traces of dachshund ancestry—short, bent legs, long body, &c.—more or less marked. The in-bred highly specialised individual has proved prepotent when crossed with the more or less generalised types which, judging from the statements of Lucas Debes (1623–1670) and Landt, have been somewhat cross-bred for at least two and a half centuries. We are apt to forget factors of the kind when discussing the breeds of domestic animals, and also when investigating the different races of men, but it should be remembered that they are of the very greatest importance in both lines of inquiry. Nelson Annandale.

34 Charlotte Square, Edinburgh.

Insular Races of Animals and Plants.

If we accept the view that species are such by virtue of segregation, and consider subspecies to be groups as yet imperfectly segregated, we seem logically bound to regard insular forms as valid species. According to this way of looking at the matter, a subspecies is in biology what a peninsula is in geography, while a species corresponds to an island. Hence it follows that many subspecies are far more widely distributed and for most purposes more important than many distinct species; just as many peninsulas are more important than the small islands off their coasts.

While it appears illogical to treat insular races as subspecies, there are difficulties in the way of regarding them all as distinct species. In former years, the most distinct were so recognised, and the others were simply ignored. This practice, while it smoothed the way for the systematist, deprived us of the use of a large body of facts of the greatest possible interest to the evolutionist, and the time has come when it must be given up. As a result of the new methods, the number of "species" recognised is increasing very rapidly, as shown, for example, by the description of seventy new Malayan mammals in a single paper by Mr. G. S. Miller, jun. Many of the "species" described in this paper are excessively similar and yet distinguishable, and inhabit different islands. It is evident that one could take a map of the Malay Archipelago and prophesy with some degree of accuracy the number of insular species of Mus and some other genera awaiting discovery by simply counting the islands, eliminating those too closely adjacent. In mountain regions something of the same sort is found, the tops of the mountains or mountain ranges serving the same purpose as islands. For freshwater organisms, lakes and river systems afford similar phenomena, as shown, for example, by the races or species of Salmonidæ.

The objections to the recognition of all these isolated forms as valid species are two. First, their extreme similarity in many instances, and second, the specific name does not indicate the immediate relationships of the form. It has seemed to me that these difficulties might be overcome by the recognition of a new category, for which the name "idiomorph" suggested itself. This name may be objectionable on account of the term idiomorphic, used in crystallography, and it is probable that someone can think of a better. If it is accepted, it may be abbreviated to "id.," as "var." is written for variety, and "subsp." for subspecies.

To illustrate the different methods, we may take certain bats of the genus Chilonycteris, found in the Greater Antilles, using the facts recently published by Mr. Rehn.

Graphic Methods in an Educational Course in Mechanics.

I AM glad to have succeeded in calling forth some correspondence on this subject. But since I have evidently failed to make my views clear, may I briefly restate my contention?

By an educational course in mechanics, I mean a course intended to teach a beginner the principles of mechanics; a course that will leave him properly equipped for more technical work.

By "analytical methods" I mean those methods in which we resolve forces and take moments about axes. Working diagrams and plotted curves (as is quite clearly implied or stated in my former letter) would accompany such work, and would not come under the head of graphic statics.

By "graphic methods" I mean those methods that depend on accurate drawing only, there being no calculation; methods in which "resolution" is replaced by the drawing of force polygons, and "taking moments" by the drawing of funicular polygons.

I advocated the exclusive use of the former methods in bringing the beginner up to the desired point at which there would no longer be danger of confusion of ideas as to principles. Such methods demand the use of simple equations and of a little elementary trigonometry.

Mr. Milne, I see, agrees with me in the main. I cannot, however, agree with him in his view that the employment of analytical methods implies that the teaching is not to be experimental, or leads to impressing on the pupil the idea that "statics is practically useless." Surely he would find "*resolving*" and "*taking moments*" more practical than drawing polygons of forces and funicular polygons in introducing a beginner to the action of machines, to matters of friction, to the nature of bending moments and shearing forces, to the torsion of shafts, and, indeed, to most of the problems of practical mechanics.

Even in the case of "statics of structures," if we limit ourselves (as I do here) to such a range as will be sufficient to make the principles clear, there is much to be said for the analytical "*method of sections*"; and if this be employed there is less temptation to present to the beginner the *un*practical "weightless frame, loaded at the joints only." However, in this branch of mechanics, graphic methods must be employed sooner or later when the learner passes beyond the simpler forms of structures.

Mr. Trotter has quite misunderstood me! He speaks much about (or against?) mathematics; says that my pupils should "emerge as mathematicians"; and refers (deprecatingly?) to "wranglers."

I cannot see that the employment, with beginners, of the methods of *resolution* and *taking moments* would produce a race of wranglers, any more than that the employment of graphic methods would produce a race of geometricians or artists.

Further, he considers me as opposed to the use of diagrams, and as preferring formulæ to explanations given in "quite ordinary language"; and he asks (indignantly?) whether I "would deny the use of a piece of string on a globe to explain great circle sailing?" I may state briefly that I am not a mathematician, that I am fond of diagrams, that I delight in simple language, and that I would give two pieces of string to any pupil who had serious aims in view. I do not think that the above were quite reasonable deductions from my letter.

I do not wish in my turn to misunderstand Mr. Trotter. But I gather from the second paragraph of his letter (vol. lxx. p. 81) that he claims the use of "quite ordinary language" as the prerogative of those teachers who use graphic methods in preference to the analytical methods of "resolution" and "taking moments"? I gather also, from the last paragraph, that, in his opinion, *to resolve forces* and *to take moments about axes* "confuse learners of statics"; and that these analytical methods are a failure when applied to dynamics? Certainly there is here a real difference of opinion between Mr. Trotter and myself.

Devonport, May 28. W. LARDEN.

THE graphic methods are the complement of the analytical, and a mind brought up on either to the exclusion of the other is but half trained. I agree with Mr. Milne that the best results are obtained when the two methods are used side by side. But there is another and potent reason for including graphic methods in an elementary course; they can to a great extent be used at an earlier stage and before the student has proceeded far in his mathematical training. The triangle of forces is practically the only principle involved, and if this is satisfactorily taught, so that in any practical application the student can write out clearly an explanation of his diagram showing what the different lines represent, he will then proceed naturally to the analytical methods of *resolving* and *taking moments*. But he will never abandon the graphic methods, which should now be developed simultaneously with the analytical. His mastery of the two, with the analytical, as I think, resting on the graphic, will give him greater resourcefulness than he would be likely to obtain from an exclusive use of one method.

I want to see the study of mechanics, even in its elementary stages, brought into closer union with practical requirements, and the barrier which usually separates theoretical from applied mechanics to a considerable extent removed. The inclusion of graphic methods tends to prevent the discussion of fantastical problems invented by the mathematician from usurping the consideration of the more practical kinds required by the engineer. In the elementary work it is not usual to take account of the internal forces which are called into play when any solid is in equilibrium under external forces. I think that the stresses induced in a bar of no appreciable weight by forces applied at its extremities should be considered at a very early stage, and then the student may work easy problems on the equilibrium of simple frames. Of course these problems are all more or less idealised, but they will serve to show him that he is at work upon something of practical value, and he will not fail to grasp and appreciate it. W. J. DOBBS.

East Putney, May 27.

The Drumming of the Snipe.

IT is disputed whether the snipe's drumming—a curious noise, suggestive of a miniature threshing machine—is made by the bird with its wings or by its tail, or by both wings and tail. Some recent observations incline me strongly to believe that the tail plays at any rate the more important part. During the performance the bird flies at a great height round and round in a wide sweeping circle. At intervals he makes a sudden and rapid descent, holding his wings partly flexed and his tail spread to its full extent. The outermost tail feather on either side points outward at a greater angle than those adjoining it, so that when the bird is watched through a good field glass daylight shows between it and the next; and, if I am right in my view, the drumming sound is due to the rush of air against this isolated feather. The snipe's tail feathers seem so puny that it is at first difficult to believe that they can produce so great a result. But if an outer one be taken—it is slightly scimitar-shaped with the outer web much reduced—and swung rapidly through the air, the drumming noise may be distinctly heard, though it seems but a very faint echo of the loud throbbing hum that startles one when it suddenly descends from an ethereal height, and the small bird is descried, hardly more than a speck to the naked eye, circling round in wild career, and now and then swooping headlong downwards and thrilling the air with his weird music. F. W. HEADLEY.

Haileybury.

THE PRESENT POSITION OF GEODESY.

THE article by Commandant Bourgeois in the *Revue Générale des Sciences* for April 30, on the present position of geodetic science is both instructive and useful with reference to those problems in geodesy which are just now before the scientific public of this country. There is, in the first place, a notable scheme for the construction of a geodetic arc in Africa which shall extend from the Cape to Cairo. Of this Commandant Bourgeois has taken due note, entering rather fully into the details of such difficulties as its projectors may find in the way of its successful accomplishment. There is also an agitation recently started amongst astronomers and surveyors, which has for its object the revision of the geodetic triangulation of England in order that it may be brought into line, scientifically, with the geodetic triangulation of adjoining countries, and take its place (as it should) as a link in more than one European system of which the value would be largely increased by this extension. Of this Commandant Bourgeois takes no note (probably because he is unaware of its existence), nor does he concern himself with any past achievements in the field of geodesy in which England has borne a part either at home or in India.

The object of the article is to place before the reader the effect of fresh inventions and new methods in developing existing geodetic projects, but it would have added much to the interest of it if so competent an expert as Commandant Bourgeois had written something about the change which has come over the objective of geodetic science which justifies its continued application to modern fields of surveying. These are utilitarian days, and seeing that the science of geodesy long ago evolved all the necessary factors for the reduction of astronomical and terrestrial observations by giving us certain mathematical formulæ based on the measurement and form of the earth, and that no subsequent investigations will ever seriously affect those deductions, it may well be doubted if any State financial assistance would be justifiable for the mere purpose of refining and polishing the results of what would be a purely abstract scientific inquiry. Geodetic arcs measured simply for the purpose of ascertaining the nature of certain eccentricities in the figure of the globe will no longer be regarded as worthy of the saving grace of State financial support, and it will remain for their projectors to prove that some other and more practical end is to be served by them if they wish for substantial recognition.

There is, of course, another (and an insufficiently appreciated) end to be served by such exact scientific processes as are involved in the measurement of a "great arc"; and if we drop the somewhat misleading term "geodetic," and simply appeal to the absolute necessity for a strong initial backbone of first-class triangulation as the basis of every survey scheme of any consequence at all—a backbone which will support the weight of any subsequent superstructure of looser and more rapid forms of triangulation which may be built upon it, and thus give solidity and homogeneity to the whole mapping of a vast area (such as Africa, for instance), we only indicate the same thing under a far more practical and intelligible form. All surveyors are agreed as to the necessity for such an initial backbone, although perhaps opinions may differ as to how far it should be extended. The great value of Commandant Bourgeois's article lies in this—that he shows clearly and concisely how the best possible scientific results may be obtained by means which not long ago were unattainable, and which involve half the expense, with (possibly) double the accuracy of those older methods which cost the country so much in the past, and (in the case of England, at least) have not proved satisfactory in the end.

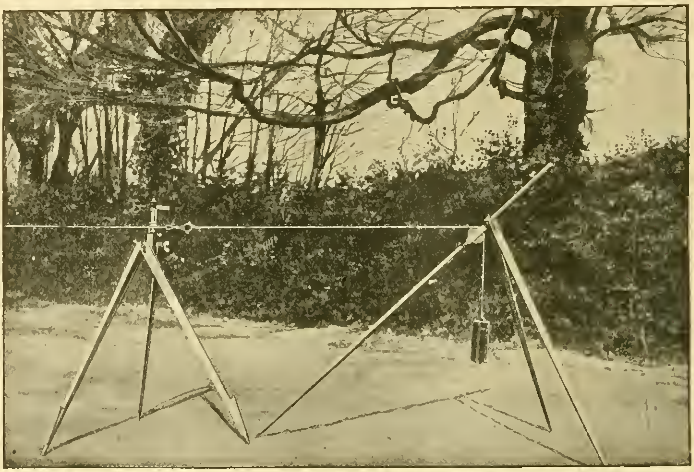

Fig. 1.—Jaderin apparatus placed in position for base measurement.

The Jäderin apparatus for base measurements, and the application of the French metal "invar" (an amalgam of 64 steel to 36 nickel) to it, is perhaps the most important of all recent improvements in the process of constructing a primary, or "first-class," triangulation. The old, clumsy, and inconvenient method of measurement by compensation bars has, we hope, disappeared for ever. The Jäderin tape has been exhaustively tested under other conditions than those mentioned by Commandant Bourgeois, and it has been found to stand the test of extremes of climate quite sufficiently well. The author indeed advocates its use for the measurement of long bases in supersession of the system of extension by triangulation from a short one. The rapidity and accuracy with which this method can be applied to the base measurements connected with a long series of principal triangulation is instanced in the case of the North American meridional arc, which has been measured on the 98th degree of west longitude. In this instance nine bases were measured in one field-season

lasting six months. Five tapes were made use of, all five being tested over one kilometre of distance to determine their relative equations. These may be expressed by 1/690,000 maximum and 1/1,200,000 minimum of probable error. Altogether more than 69 kilometres of base measurement were effected at a cost of 160 dollars per kilo. Commandant Bourgeois maintains that the limits of probable error in linear measurement are in satisfactory relation to the limits of probable error in the angular measurements of the instrument used for triangulation. But he does not fully describe the latter. One of the essential features in modern principal triangulation is the employment of instruments of half the size and about one quarter the weight of those which were deemed necessary twenty-five years ago. Improvements in graduation and, above all, the introduction of the micrometer eye-piece have so far added to the accuracy of modern theodolites that a 12-inch instrument in India now takes the place of the 24-inch

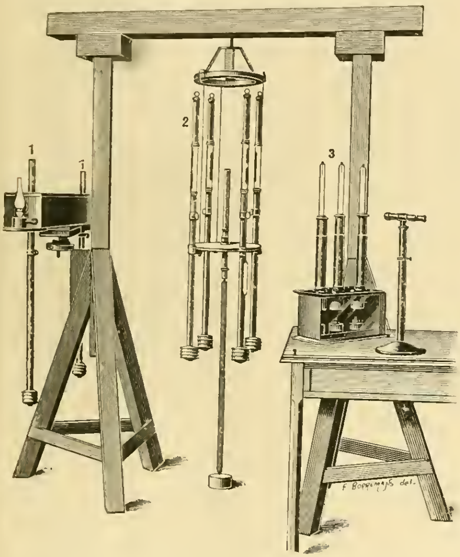

FIG. 2.—Apparatus of M. Hecker for measuring the intensity of gravity in the open sea by comparison of the readings of the barometer (1 and 2) and hypsometer (3).

and 36-inch instruments formerly used. Surveyors will probably have their own opinions as to the methods of observation indicated by Commandant Bourgeois. The German method approved by him, and adopted in France, appears to contemplate certain irregularities in the signals for observation which ought not to exist. It will probably be found that the system of observing should be adapted to the atmospheric peculiarities of the district in which the observations are taken. But the German method is well worth the careful attention of English surveyors.

That part of the article which deals with the deflection of the plumb line and the intensity of the force of gravity, has a most interesting reference to M. Hecker's apparatus for investigating these problems in ocean spaces by means of a comparison between barometric and hypsometric observations; the general result of such observations taken in the Atlantic between Bahia and Lisbon being to prove that there is no great variation between the results determined in the deep sea and on the Continent. M. Hecker is still engaged in this branch of geodetic inquiry.

The reference to the African are now contemplated, and to an equatorial arc recently measured by French scientists in the Republic of Equador in South America, should be studied together, for the experience obtained in the latter points some useful morals for the consideration of those who may undertake the measurement of the former. The physical conditions of the country and the variations of an unusually tempestuous season presented but small obstruction to the progress of the work compared to the hostility of the indigenous Indians. Stations were destroyed and markstones uprooted with such persistent animosity in Equador that a great part of the observations had to be repeated. If principal, or geodetic, triangulation is to serve the purpose of scientific investigation only, the destruction of the observing stations would not be of so much consequence, when once the chain of triangles composing the arc was finally complete. But it is obvious that if any useful ulterior purpose of map-making is to be served by the expensive process of laying down a backbone of well-fixed points, it is all important that every station and every markstone should be preserved with the utmost care. In spite of most elaborate precautions these most necessary indications are sometimes lost in India, and fresh observations have to be made in order to redetermine their position. Isolation of the instrument during the process of observing is almost always imperative, although it occasionally happens that a considerable area of hard rock exists of sufficient stability to serve as the basis of the observing station without involving any artificial isolation. But the building of isolating pillars and the erection of cairns over them for protection almost inevitably attracts the attention of the tribespeople in the neighbourhood, and the result is subsequent destruction.

The only way to safeguard with any prospect of success against the utter waste of time and money which is involved by the destruction of signals and markstones, after the triangulation has been effected with scientific precision and rigorous methods of observation, is to fix, *pari passu* with the principal triangulation, a large number of secondary points scattered over the face of the country, consisting of natural features which it is impossible to remove, or for Indians to identify. It cannot but happen that principal triangulation carried through an arc of 65° of amplitude in such a country as Africa will involve a great deal of native hostility, and its preservation finally will be almost an impossibility. It will be most necessary, therefore, to take all classes of observations that have eventually to be taken from any one station at one and the same time of occupation. It may indeed be an open question whether one or two short principal series from the coast westward, following, say, the Zambesi and the Uganda Railway to the meridian of 30° E., would not sufficiently answer the utilitarian purposes of a basis for African surveys were they connected by secondary or even tertiary triangulation at their extremities, and the connection pushed northward to meet a third principal series on the Nile. This, however, is but a side issue prompted by the perusal of the admirable article in the *Revue Générale des Sciences*.

One especially interesting result of the observations for level deflection taken in connection with the Equador arc, is an indication that the compensation of exterior mass by interior deficiency, or want of density, indicated by such observations at certain Himalayan stations, does not exist in the equatorial region of the Andes. T. H. H.

THE INTERNATIONAL ASSOCIATION OF ACADEMIES.

THE delegates of the International Association of Academies met at the Royal Society on Wednesday, May 25, and Sir Michael Foster, K.C.B., was elected president of the general assembly. A number of resolutions were adopted at that and other business meetings, and are incorporated in the official report of the proceedings, but this has not yet reached us.

The delegates were received by the King at Windsor on May 25, and attended a conversazione at the University of London on May 27. Throughout the evening many objects of scientific interest were on view, but, with a few exceptions, the exhibits were the same as those shown at the recent conversazione of the Royal Society, and already described (May 19, p. 70). Among the additional exhibits were the following:—Horse face-pieces and other ornaments from the trappings of cart-horses, Miss L. Eckenstein; prehistoric Egyptian stone vases, Mr. Randolph Berens; (1) Japanese paintings (Kakemono), (2) photomicrographs of iron and steel, Prof. W. Gowland; series of Egyptian beads, Prof. W. M. Flinders Petrie, F.R.S.; mimetic resemblance of the different forms of a single species to two or three different models, Prof. E. B. Poulton, F.R.S.; seed-bearing plants from the Coal-measures, Mr. E. A. Newell Arber, Miss M. Benson, Mr. R. Kidston, F.R.S., Prof. F. W. Oliver, and Dr. D. H. Scott, F.R.S.; paradoxical shadows in a non-homocentric beam of light, Prof. Silvanus P. Thompson, F.R.S.; freshwater phytoplankton from various parts of England and Ceylon, Dr. F. E. Fritsch; series of rubbings of brasses, Hilda Flinders Petrie; stone implements and model of raft from the lowlands of eastern Bolivia, Dr. J. W. Evans; (1) model of steam ship *Turbinia*, (2) (*a*) 4 kilowatt turbine-driven dynamo, (*b*) model of 4000 kilowatt turbine-driven alternator, (3) turbo-blowing engines, the Parsons Marine Steam Turbine Company, Limited.

On Saturday the foreign delegates visited Oxford and Cambridge in two parties, and the honorary degrees referred to elsewhere (p. 115) were conferred by the universities. A complimentary banquet to the delegates was given at the Mansion House on Monday by the Lord Mayor of London.

ROBERT McLACHLAN, F.R.S.

THE death of Robert McLachlan, familiarly known to his friends as "Mac," removes from our midst one of the most prominent characters in the London entomological world during the last half-century. He joined the Entomological Society as long ago as 1858, and always interested himself greatly in its welfare, having successively filled the offices of secretary and president, and still holding (as he had done for many years past) the office of treasurer at the time of his death. Till the last few months, when failing health compelled his absence, he was most regular in his attendance at the meetings. He was also one of the five original founders of the *Entomologists' Monthly Magazine* (in 1864), and up to the last was still one of the acting editors—the last of the founders—the other four having all died or retired many years ago.

Mr. McLachlan was the son of a ship's-chandler on Tower Hill, whose instruments were very highly esteemed by the mercantile community. Being possessed of independent means, he devoted his life to entomology, though, as a child, he tells us, in some autobiographical notes in his Presidential Address to the Entomological Society, in January, 1887, he had taken most interest in botany. He made one voyage to the Southern Seas in 1855, and finally settled himself at Lewisham, near his intimate friend Stainton, occasionally visiting various parts of the British Isles, and the Continent of Europe; especially when any entomological congresses were on foot, which he was very fond of attending. Like most of his contemporaries, Mr. McLachlan commenced his entomological studies with British Lepidoptera, as we learn from the list of entomologists in the *Entomologists' Annual* for 1858, where his name first appears, at which time he was living at Forest Hill; but he soon turned his attention to Neuroptera, the study of which order in England received a great impetus just then by Dr. Hagen's papers in successive *Annuals*. McLachlan especially attached himself to the Trichoptera, or caddis-flies, which he studied largely from an anatomical standpoint, often, in later years, speaking contemptuously of coloured figures of butterflies as being only fit for children. He contributed many important papers on British and foreign Neuroptera and Trichoptera to entomological journals, and being in constant communication with the leading neuropticists at home and abroad, was able to bring together one of the finest collections in the world in his special groups, part of which, at least we hope, will find a permanent home at the Natural History Museum, South Kensington. Part of the national collections of Neuroptera, previously catalogued by Walker, were rearranged and annotated by McLachlan. He compiled (with the exception of the Ephemeridæ, which were undertaken by the Rev. A. E. Eaton) the catalogue of British Neuroptera published by the Entomological Society of London in 1870, and he also compiled the reports on Neuroptera and Orthoptera for the *Zoological Record* from 1869 to 1885. His most important scientific work was his "Monographic Revision and Synopsis of the Trichoptera of the European Fauna" (1874–1884), but his smaller publications are extremely numerous. Mr. McLachlan was never married. He died at his residence at Lewisham at the age of sixty-seven, on May 23, to the regret of a wide circle of entomological friends and acquaintances. W. F. K.

ÉMILE SARRAU.

THE great advance in modern artillery and ballistics is due principally to the efforts of the French Government, determined not to be caught a second time at a military disadvantage. The progress has been made in the most rapid and economical manner by the appointment of committees, composed of experts chosen for their exact scientific knowledge, such as Sebert, Berthelot, Vieille, to investigate the problem and to solve the details by a judicious combination of theory and experiment.

Chief among these scientific experts, Sarrau was also the director of the Government factories of modern explosives, and at the same time professor of the theory at the École Polytechnique in Paris, and the School of Application at Fontainebleau.

We can follow the general course of his lectures by his published books on the theory of explosives; these will emphasise the lead taken by the French, and their contempt for any secretiveness about the laws of nature involved in the corresponding phenomena.

His books and other practical achievements serve to show his success in design and invention; at the same time the obituary notices by his colleagues tell us how highly he was appreciated and esteemed as a teacher by his classes of pupils.

NOTES.

THE annual visitation of the Royal Observatory, Greenwich, will be held on Saturday next, June 4.

THE following have been elected honorary and foreign members of the Chemical Society:—Prof. A. H. Becquerel, Prof. C. A. L. de Bruyn, Prof. F. W. Clarke, Madame Curie, Prof. C. T. Liebermann and Prof. E. W. Morley.

A DEPUTATION from the Yorkshire Philosophical Society will wait upon the York City Council on June 6 with the object of asking the corporation to issue an invitation to the British Association to make York the meeting place in 1906.

THE death is announced of M. Charles Soret, formerly rector of the University of Geneva, and a member of council of the French Physical Society.

THE Lombardy *Rendiconti* announces the death of Prof. Amato Amati, one of the most energetic educationists in Italy, and the author of works on Dante and on geography.

THE death is announced of M. E. D. del Castillo, who prepared a flora of the French islands of Polynesia and described a portion of the plants brought from Madagascar by M. Alfred Grandidier.

AT a meeting of the General Medical Council on Tuesday, the following resolution was passed:—"That the president (with the chairman of the Pharmacopœia Committee) be requested to inform the Lord President of the Privy Council that in the opinion of the council it is desirable that after a sufficient period, to be fixed by law, the metric system of weights and measures should become the one legal system for the preparation and dispensing of drugs and medicines; that the council would view with favour the passing into law of a Bill such as that now before Parliament entitled the 'Weights and Measures (Metric System) Bill'; and that in that event the council would be prepared to take all necessary steps to give effect to the law by making the proper modifications in the 'British Pharmacopœia.'"

A REUTER message from Wellington, New Zealand, reports that the King has sent the following telegram to Captain Scott, leader of the National Antarctic Expedition:—"I have read with interest your report, which Sir Clements Markham sent me. I congratulate you and your gallant crew on your splendid achievements, and wish the *Discovery* a safe journey home. I hope to see you on your return to England."

IN a letter to the secretary of the Scottish Antarctic Expedition, says the *Times*, Mr. W. S. Bruce, the leader of the expedition, remarks:—"We have reached the south-eastern extremity of the Weddell Sea, discovering there a great barrier of ice, part of the Antarctic Continent. We have gone 215 miles further south than last year, and 180 further than Ross in this part of the Antarctic regions. We got beset here in 74° S., 23° W., and were frozen in for a week, from the 7th to the 12th of March. When we got out by chance I thought it wisest not to proceed further in trying to get south and west, but to continue our programme to the north-east. We have sounded in depths up to 2900 fathoms and trawled in depths of 2660 fathoms (where Ross marks 4000 fathoms, no bottom)."

A REUTER message from Rome reports that the Marconi wireless telegraph stations at Bari and Antivari (Montenegro) have now been erected for some time, and are in regular working order. The high power station at Coltano (Pisa), near the Royal farm of San Rossore, will be the largest in the world, and will be built entirely of stone. It will be ready in August or September, after which the engines and other apparatus will be installed, so that it may begin working not later than the beginning of 1905. The Coltano station will be able to communicate with Great Britain, Canada, the United States, and the Netherlands, as well as with all vessels in the Mediterranean, the Baltic, the Red Sea, the Atlantic Ocean, and the Indian Ocean.

THE eighty-seventh annual meeting of the Société helvétique des Sciences naturelles will be held at Winterhour from July 30 to August 2. The business of the association will be transacted in seven sections as follows:—mineralogy and geology, botany, zoology, chemistry, physics and mathematics, medicine, and civil engineering. The annual meetings of the Swiss societies of geology, botany, zoology, chemistry and of the Société zurichoise de Physique will be held at Winterhour at the same time. The president of the association will be Prof. J. Weber, the vice-president Prof. E. Lüdin, and the secretary M. E. Zwingli, to whom all communications should be addressed at Geiselweidstrasse, Winterhour.

IN recent numbers of NATURE (March 24 and April 21) Prof. Nagaoka and Prof. Franklin have described methods for demonstrating the change of length of iron wire by magnetisation. Prof. J. C. McLennan, University of Toronto, writes to say that a simple and satisfactory method of exhibiting this phenomenon is described in the *Physical Review*, vol. iv., No. 35, July, 1898, and consists in the use of an optical lever attached to the test specimen.

MR. T. TERADA writes to us from the College of Science, Tokyo, to direct attention to an optical illusion observed when lycopodium powder strewn on the surface of water is made to gyrate by a jet of air. After the whirling powder has been fixedly regarded for some time, and the eyes are directed to an adjoining table, the surface of the table appears to move in a direction contrary to that of the lycopodium.

DR. D. PACINI sends us from Rome an account of careful experiments made by him with the object of observing the effects of *n*-rays described by M. Blondlot and other investigators. Though his observations were made under very favourable conditions, he was unable to detect any increase of luminosity of a phosphorescent screen caused by unknown rays from strained or tempered steel, an Auer lamp, a Nernst lamp, sound vibrations, or a magnetic field, though various French observers have affirmed that in each of these cases *n*-rays are emitted which produce an effect upon the screen.

IN the course of an interview reported in the *Westminster Gazette* of Friday last, Lord Kelvin is reported to have expressed himself as being decidedly of the opinion that the source of energy of the heat emitted by radium is not in the element itself. He remarked:—"It seems to me absolutely certain that if emission of heat at the rate of 90 calories per gram per hour found by Curie at ordinary temperature, or even at the lower rate of 38 found by Dewar and Curie from a specimen of radium at the temperature of liquid oxygen, can go on month after month, energy must somehow be supplied from without."

A PAPER on crystalline glazes and their application to the decoration of pottery, read before the Society of Arts by Mr. William Burton, and printed in the current number (May 27) of the *Journal* of the society, is a noteworthy contribution both to the science and the art of pottery. By applying scientific knowledge and method to the production

of glazes on pottery, Mr. Burton has been able to obtain with precision a variety of crystalline and opalescent effects of decided novelty and beauty. This has only been rendered possible by making many experiments to discover the influence of the materials and the temperature on the effects produced and by having each stage of the process under perfect control. In one of the new glazes produced in this way, artificial crystals which are developed in full perfection at temperatures from 1000° C. to 1030° C. are reabsorbed into the glaze as the temperature is increased, and remarkable changes of colour are assumed until at a temperature of 1070° C. the crystals are entirely reabsorbed. The crystalline effects produced at the different temperatures are of interest to the mineralogist, and the striking appearance of the pottery upon which the crystals are developed demonstrates the advantages of the application of science to industrial art.

THE first excursion of the summer session of the Belfast Naturalists' Field Club was held on May 21, when 167 members and their friends visited Hillsborough to explore and examine the demesne of the Marquis of Downshire. Though this is the largest attendance at any one of the meetings of the society, the Belfast Naturalists' Field Club is, in the forty-second year of its existence, one of the most active Irish societies devoted to the practical study of natural history. The main object of the club is to interest people generally in the study of natural objects, and this is, of course, all that can be accomplished in gatherings of the size mentioned. We are glad to know, however, that many of the members have been able, by private additional visits, to add to the scientific knowledge of the district. The honorary secretaries of the club are Mr. Nevin H. Foster, Hillsborough, co. Down, and Mr. James Orr, 17 Garfield Street, Belfast.

THE *Zeitschrift der Gesellschaft für Erdkunde* contains an extremely interesting report of a lecture on western Asia Minor by Dr. A. Philippson. Having completed his work in Greece, Dr. Philippson has undertaken the investigation of this little known region, which is of special interest to Germany on account of the Anatolian Railway. His paper summarises the results of explorations up to the present time.

UNDER the title "A Case of Geographic Influence upon Human Affairs," Mr. George D. Hubbard discusses the results of glaciation in a limited portion of the State of Illinois in the *Bulletin* of the American Geographical Society. The subject is dealt with "from the point of view of geographic influence upon plants, crops, and animals, and upon man's distribution, occupations, successes, and failures," and the paper is a good illustration of the method of treating the geological element in questions of the kind.

IN an article on the developmental changes in some common Devonian brachiopods (*Amer. Journ. Science*, April), Mr. Percy E. Raymond describes, from abundant material, the life-changes undergone in a number of species of brachiopods, with especial reference to the character of the nepionic shell, the development of the pedicle tube and the deltidial plates, and the acquirement of surface characters. The specimens were obtained from the Moscow (Hamilton) shales, near Canandaigua Lake, New York. They occurred in layers of impure limestone, but were completely replaced by silica, and when the rock was etched in acid the fossils were left in a remarkably perfect condition. The fauna comprised many forms of invertebrates, besides brachiopods, and included many individuals in immature stages.

A RESTORATION of the Ornithosaurian Pteranodon has been prepared by Mr. G. F. Eaton, as the contribution of the Department of Vertebrate Palæontology of the Yale Museum to the St. Louis Exhibition. Particulars, accompanied by a half-tone engraving (which we are enabled to reproduce), have been published in the *American Journal of Science* (April). The genus was originally described by Marsh from the Cretaceous rocks of North America, but further details of its structure have since been obtained. Mr. Eaton points out that the sclerotic circle is composed of twelve thin plates of bone arranged with overlapping edges, so as to form a hollow truncate cone, similar in shape to the avian sclerotic circle. With regard to the vertebræ, there are nine cervicals. In the dorsal series are included eight vertebræ, anchylosed to form the notarium, and four free dorsals intervening between the notarium and the sacrum. By assuming that the first four vertebræ of the sacral series (in the broader sense) are homologues of the lumbars of other groups, the total number of presacral vertebræ would appear to be twenty-five. This compares closely with the supposed number of presacrals in the Eusuchia.

FIG. 1.—Restoration of *Pteranodon longiceps*, Marsh. Scale an inch to about 3 feet.

IN the second part of vol. xxxvi. of the *Memoirs* of the Russian Geographical Society, for general geography, Prof. N. Zarudnyi gives the second part of the account of his journey to eastern Persia. It contains a description of the 421 species of birds found by him, with the addition of a few species previously observed by Dr. Blanford and Dr. Aitchison. It would be premature as yet to draw any general conclusions concerning the relations between the avifauna of eastern Persia and the other parts of the Iran plateau and the Turan lowlands. Consequently, the Russian ornithologist only gives a description of each species, with interesting notes concerning the habits of the species and its distribution. Dividing his region into six districts, he gives the lists of nesting and temporary visiting birds for each district separately.

THE larval eyes of the mollusc Chiton and their ultimate fate form the subject of an article by Mr. H. Heath in the March issue of the *Proceedings* of the Philadelphia Academy.

In a recent issue (vol. lxxii., No. 3) of the *Journal* of the Asiatic Society of Bengal, Mr. E. P. Stebbing records the occurrence in the Himalaya of a beetle of the genus Thanasimus, a discovery which may be of some commercial importance, owing to the fact that these insects feed on the bark-beetles so destructive to timber.

A feature in the report of the proceedings of the sixteenth annual meeting of the U.S. Association of Economic Entomologists (Ent. Divis. Agric. Dept., *Bull.* No. 46), is an address on insect photography by Mr. M. V. Slingerland. While urging the importance of this comparatively new application of photography, the author points out that many of the replicas of photographs published in current literature are of a very inferior type.

In the May number of the *Zoologist* the editor continues his notes on the influence of rivers on animal distribution, dealing, first, with their active, and, secondly, with their passive effect as dispersers. A very large number of cases are cited where animals—singly or in parties—have been involuntarily carried down by rivers, while in the second part the author has been equally industrious in collecting records of instances where animals have swum rivers of considerable breadth.

Invertebrates form the subject of the four articles in the latest issue (vol. lxxvi., part iv.) of the *Zeitschrift für wissenschaftliche Zoologie*. Messrs. Schuberg and Schröder describe a new thread-worm infesting the muscles of leaches of the genus Nephelis. The spermatogenesis of sponges and cœlenterates is discussed by Mr. W. Görich, while Mr. C. Julin gives the result of his investigations into the phylogeny of tunicates, and Dr. H. Simroth describes a remarkable new slug, *Ostracolethe fruhstorferi*, from Tonquin, and its bearing on the classification of gastropods.

According to the classification generally in use in this country, fishes are divided into the four subclasses Elasmobranchii, Holocephali, Dipnoi and Teleostomi, while the Palæozoic Ostracodermi (Pteraspis, Cephalaspis, Pterichthys, &c.) are placed in a class by themselves. Mr. C. T. Regan, of the British Museum, in a paper on the phylogeny of the Teleostomi, published in the May number of the *Annals and Magazine of Natural History*, has, however, arrived at the conclusion that a much simpler scheme is advisable, and that it will suffice to divide the class (inclusive of the Ostracodermi) into the two groups Chondropterygii and Teleostomi, the former including the Elasmobranchii and Holocephali, together with Pteraspis and its allies, and the latter all the rest. The most primitive group of Teleostomi is considered to be the Chondrostei (sturgeons and Palæoniscidæ), from which all the others are derived. One branch gave rise to the Crossopterygii, from which in turn sprang the Dipnoi (Dipneusti), the author regarding the resemblance which has long been known to exist between the fins of the two latter groups as over-riding the differences in the skull-structure. The Teleostei take origin as a separate branch from the Chondropterygii. The most pronounced departure from the views of others is, however, the brigading of the Ostracodermi (exclusive of Pteraspis, which is regarded as a chondropterygian) with the Arthrodira (Coccosteus, &c., generally grouped in the Dipnoi), as an offshoot of the Crossopterygii, under the title of Placodermi. Mr. Regan will, we think, have considerable difficulty in persuading palæontologists to accept this part, at any rate, of his scheme.

It is stated in *La Nature* (May 28) that Dr. Chaput has found that peroxide of zinc (discovered by Elvas) proves an efficient substitute for peroxide of hydrogen for dermatological and other uses, and is much less irritating than the last named substance.

The April issue of the *Journal of Hygiene* (vol. iv., No. 2) contains a number of most interesting and important contributions. Staff Surgeon Dalton, R.N., and Dr. Eyre have investigated the thermal death point of the *Micrococcus meletensis*, which proves to be 57°·5 C. They describe an apparatus whereby constant temperatures may be maintained, and suggest standard conditions for the determination of the thermal death points of micro-organisms. Dr. Houston, in a paper on the bacteriological examination of oysters and estuarial waters, details the main facts obtained during an investigation undertaken on behalf of the Royal Commission on Sewage Disposal. Dr. Nuttall and Mr. Inchley describe an improved method for measuring the amount of precipitum in connection with tests with precipitating antisera. Dr. Stevenson suggests a method of estimating future populations. Messrs. Bowhill and Le Doux give a note on a case of piroplasmosis canis, a tick disease of the dog, occurring near Grahamstown, and Dr. Nuttall describes the disease in a lengthy article illustrated with photos and temperature charts. Lastly, Dr. Graham Smith describes very fully a study of diphtheria bacilli isolated from 113 individuals during an outbreak of diphtheria at Cambridge in 1903.

The fifth volume (second series) of the *Publications* of the U.S.A. Naval Observatory is devoted to a complete record of the meteorological observations made at the new Naval Observatory, Georgetown Heights, during the years 1893–1902 inclusive. After a preliminary description of each of the instruments used, the readings of the barometer and the wet and dry bulb thermometers, and the cloud and wind observations at three-hourly intervals during each day are given. The whole of the results are summarised in an exhaustive series of tables which conclude the volume.

In the *Annals of Botany* for January, Mr. Harold Wager discusses the function of the nucleolus in plants and animals, and, basing his deductions upon the investigation of the nucleus in the cells of the root-apex of Phaseolus, he comes to the conclusion that the nucleolus is intimately bound up with the formation of the chromosomes, and that there is a definite continuity of nuclear substance from mother-nucleus to daughter-nucleus through the chromosomes. Mr. Wager has also attacked the problem of the cell structure in the Cyanophyceæ, and in a preliminary paper communicated to the Royal Society he claims that the central body of the Cyanophyceæ is a nucleus of a simple or rudimentary type.

The second volume of the second revised and enlarged edition of Prof. W. Pfeffer's work on "Pflanzenphysiologie" (Leipzig: Engelmann; London: Williams and Norgate) has been received. The volume is chiefly concerned with transformations of energy resulting in various movements in plants.

Three pamphlets on radium and radio-activity have just been received from German publishers. One is a second edition of a useful summary, by Prof. K. Hofmann, of investigations of Becquerel and other rays from 1896 to the present time; the title is "Die radioaktiven Stoffe nach dem neuesten Stande der wissenschaftlichen Erkenntnis" (Leipzig: Barth). The same publisher has

issued a translation, by Prof. G. Siebert, of Mr. F. Soddy's Wilde lecture (see Nature, March 3, p. 418) on the evolution of matter as revealed by the radio-active elements. A translation, by Mr. E. Ruhmer, of a lecture by Mr. W. J. Hammer, delivered before the American Institute of Electrical Engineers, on radium and other radio-active substances, has been issued by the publishers of *Der Mechaniker*, Berlin.

OUR ASTRONOMICAL COLUMN.

The Extreme Ultra-Violet Spectrum of Hydrogen.—In No. 4, vol. xix., of the *Astrophysical Journal*, Mr. Theodore Lyman, of Harvard University, gives a list of wave-lengths for the lines in the extreme ultra-violet spectrum of hydrogen, first discovered by Dr. Victor Schumann. In Mr. Lyman's experiments the light from the discharge tube was transmitted through fluorite windows and a tube containing hydrogen at very low pressure, and the spectrum was formed by a concave grating ruled on speculum metal. He found that from the region about λ 1854 to about λ 1700 the spectrum is almost continuous, containing only a few faint lines. About λ 1700 there is an absorption band, the width of which seems to depend upon the purity of the hydrogen enclosed in the apparatus. Beyond λ 1650, towards the more refrangible limit of the spectrum, numerous fine lines exist, and of these Mr. Lyman has measured 134. In the table accompanying the paper the wave-lengths (to five figures) and intensities of 133 lines between λ 1033 and λ 1878 are given. It is interesting to note that the superior reflecting power of speculum metal for these short wave-lengths has been incidentally demonstrated by the use of the grating.

Variable Radial Velocity of η Piscium.—A series of spectrograms of η Piscium obtained by Prof. H. C. Lord, of Columbus (Ohio), and extending over the period December, 1901, to January, 1904, indicate that this star has a variable radial velocity of long period.

From measurements of Hγ and thirteen carefully selected iron lines the following results, among others, were obtained :—

Date	Radial vel. (Reduced to Sun)	Date	Radial vel. (Reduced to Sun)
Dec. 15, 1901 ...	+18·5 kms.	Dec. 15, 1903 ...	+ 9·5 kms.
Jan. 10, 1902 ...	+25·4 ,,	Jan. 9, 1904 ...	+10·6 ,,

The sharp definition of the lines in the spectrum of η Piscium render its radial velocity especially suitable for spectroscopic measurement, and this fact, with other confirmatory evidence, leads Prof. Lord to the conclusion that the variability is real (*Astrophysical Journal*, No. 4, vol. xix.).

Proposed New Observatories.—In a report published by the Carnegie Institution at Washington (December, 1903), a committee consisting of Profs. Boss, Campbell and Hale, which was appointed by that institution "to consider certain large projects in astronomy," strongly urge the establishment of an observing station in the southern hemisphere for the prosecution of certain definite observations which it is hoped might be completed in ten or twelve years. They also recommend that an observing station for solar investigations in an exceptionally favourable atmosphere should be established and maintained throughout one full sun-spot period (eleven years) at least. Further, they urge the construction and maintenance of a large reflector for astrophysical investigations at one, or both, of the proposed stations. These recommendations are supplemented by a detailed programme of the work that might be accomplished and a carefully prepared scheme for the necessary buildings and staffs.

In Appendix A Prof. J. W. Hussey, who was deputed to explore California and Arizona in order to determine the most suitable site for the proposed solar observatory, gives an interesting account of his search, which led to the recommendation of Mount Wilson (California) as offering the best facilities for the work. Appendix B consists of a number of letters from eminent astronomers in answer to a confidential inquiry as to their views on the establishment of the proposed observatories.

Variability of Spark Spectra.—Some interesting results have been obtained by Mr. A. S. King, of Bonn, from a long series of experiments on the variability of spark spectra with various conditions of current, discharge and environment. So far, the spark spectra of six metals, Cd, Zn, Mg, Ca, Hg and Al, have been studied under different conditions, and the results of the experiments have led to the following conclusions :—

(1) The lines of each metal may be divided into two groups according to their behaviour when the conditions are varied. The first group contains all the "series" lines and a few others, whilst the second group includes the lines for which no "series" relations have yet been discovered. (2) The lines of both groups are enhanced by capacity and weakened by self-induction, but those of the second group are much more affected in this way than those of the first. (3) Of the two "subseries" of each metal the first is much more sensitive to all changes. (4) The last members of a series are reduced more by self-induction than the first, a shift of maximum intensity towards the greater wave-lengths being produced. "Capacity" has the opposite effect.

Mr. King describes his experiments, and discusses the results in detail in a paper published in No. 4, vol. xix., of the *Astrophysical Journal*, where some of his photographs are reproduced.

Report of the Oxford University Observatory.—In the twenty-ninth annual report of the Oxford University Observatory, Prof. H. H. Turner gives a *résumé* of the work accomplished during the twelve months from May 1, 1903, to April 30, 1904. He again refers to the urgent need for a residence attached to the observatory, but on account of the general lack of funds at the university he does not press the matter.

The measurement and reduction of the plates for the Oxford section of the International Astrographic Chart is now complete, and the press copy of the work has been lodged at the Bodleian Library for safety until it is possible to raise the 2000*l*. necessary for its printing and publication. It was proposed that the experience gained by the observatory staff in the production of this work might be utilised in measuring the plates taken at one of the southern observatories where the lack of funds and instruments prohibits the completion of the work. To this end fifty plates were received from the Perth (W. Australia) Observatory, and on measuring twenty-one of them it was found that their reduction could be easily and economically carried out at Oxford.

A stereo-comparator, which is essentially an elaborate and improved stereoscope for the comparison of the star-places on any two plates of the same region, but taken at different epochs, has been presented to the observatory by Mr. C. L. Brook, and has been proved to be efficient and easily manipulated.

The Stereo-Comparator. In No. 5, vol. xii., of *Popular Astronomy*, there appears a translation of a paper communicated to the Astronomical Society of Belgium by Dr. G. van Biesbroeck, in which the author traces the evolution of, and describes, the stereo-comparator invented by Dr. Pulfrich; he also gives brief accounts of the researches wherein the instrument will prove to be an extremely useful aid. Amongst the latter he notices the study of cometary features, the detection of stellar proper motions, and the discovery of minor planets. As evidence of the comparator's efficacy in the last named field, he mentions that Dr. Pulfrich, who was totally without experience in minor planet work, not only found several asteroids which Prof. Wolf had recognised on a pair of plates taken at Heidelberg, but also discovered a new one, which the careful scrutiny of the latter observer, under the ordinary conditions, had failed to reveal.

EMERGENCE AND SUBMERGENCE OF LAND.

At the recent anniversary of the Geological Society, when the president was unable from illness to be present, his place was taken by Sir Archibald Geikie, who prepared an address for the occasion on the evidence supplied by the British Isles as to the problem of the causes of changes in the relative levels of sea and land. This address appears in full in the *Quarterly Journal* of the society, and we here reproduce it in abstract.

(i.) *Emergence.*—Geologists in the British Isles have long indulged the confident belief that Raised Beaches afford demonstrative proof of changes in the relative levels of sea and land. The abundant and striking examples of them around our coasts have been universally accepted among us as marking former sea-margins, whether the sea be supposed to have risen upon the land or the land to have been upheaved above the sea. The recurrence of precisely similar terraces along the western coast of Norway, but on a still more impressive scale, has been regarded as furnishing evidence of an extensive emergence of land, from the south of Britain to the northern end of the Scandinavian peninsula. Prof. Suess, however, seeks to show that, at least as regards the north-western coast of Norway, these opinions are based upon a misreading of the evidence. After his visit to that region, and his study of the literature of the strand-lines, there so wonderfully developed, he has come to the conclusion that the Norwegian fjords furnish no argument against his doctrine that there has been no recent upheaval of the land. He asserts that "we must interpret all the *seter* [rock-shelves] and the great majority of the terraces in the fjords of Western Norway as proofs of the retreat of the ice that once covered so much of the peninsula, and not as proofs of any oscillations of the surface of the sea, still less of any movement of the solid land." It would widen the inquiry too much to enter upon an examination of the evidence as it is presented in Scandinavia. But the author of the address, having been all his life familiar with the strand-lines of this country, and having traced those of the Norwegian coast from Bergen to Hammerfest, directed attention to one or two of the insuperable difficulties with which Prof. Suess's theoretical explanation seemed to him to be beset. The great Austrian geologist appears to have unwittingly confounded two sets of beach-lines, which differ a good deal from each other in general character, and are entirely distinct in origin. Availing himself of the remarkably full and interesting researches of Scandinavian geologists regarding the glaciation of their country, he dwells upon the importance of the terraces left by the fresh-water lakes that were dammed back by the great ice-sheet as it retired. He believes that these phenomena extended even to the Norwegian coast, and that the strand-lines of the fjords, whether in the form of platforms eroded out of the solid rock (seter) or terraces of sediment, mark former levels of lakes that filled these valleys when their mouths were blocked up with the ice-sheet. As the lowest of these strand-lines includes sands and gravels crowded with marine shells, he is compelled to admit that it marks a former sea-beach. But he endeavours to discriminate between it and the other horizontal shelves, which follow it in parallel lines at higher levels. He affirms that the latter present a series of "characters absolutely irreconcilable with what we know of the action of the sea along a shore"—such as the series of fragmentary terraces found at increasing heights inland, their absence from the parts near the general coast-line, and the breadth of the seter. He passes lightly over the fact that some of these higher terraces have yielded marine organisms which are progressively of more Arctic character, according to their altitude, and according, consequently, to the antiquity of the sediments in which they lie.

Now, according to the experience of those northern geologists who have specially studied Scandinavian glaciation, the lakes that were formed by the ponding-back of the drainage against the flanks of the ice-sheet lie to the east of the watershed of the peninsula. These observers have ascertained that when this ice-sheet was waning, it retreated eastward from the backbone of the country and lay on the eastern or Swedish slope, leaving a gradually increasing breadth of ground clear of ice. The streams flowing eastward over this liberated area had their drainage arrested against the margin of the ice; and hence arose a vast series of lakes which lasted for longer or shorter periods, until, by the continued creeping backward of the ice, their contents were drained off to lower levels. A multitude of records of old water-levels, or "strand-lines," was thus left over the surface of the country. It is the opinion of Scandinavian geologists that all the terraces not of marine origin lie within that area.

As one of the distinctive characters of the shore-lines left by the glacier-lakes, the author of the "Antlitz der Erde" cites the occurrence of the rock-shelves or platforms (seter) eroded out of the solid rock, and he refers the origin of these common features of the fjords to the daily oscillations of temperature at the surface of the lakes. A reference to the abundant examples of such rock-shelves in our own islands showed that this explanation is at least inadequate. If, however, for a moment, we grant that the strand-lines, including the seter of the Norwegian fjords, do mark levels of former fresh-water lakes, it is obvious that, in order to pond the drainage back and produce these lakes, the mouths of the fjords must have been in some way blocked up by a barrier which has disappeared. If this barrier were land-ice, as Prof. Suess appears to assume, the water would rise behind it, until, if the overflow found no escape into the Atlantic, it would pass over the watershed, and joining the various bodies of water that were there intercepted by the great Swedish ice-sheet, would eventually find its way into the Gulf of Bothnia. There would thus be two huge bodies of ice, between which the drainage was accumulated. We must remember, however, that the strand-lines are not confined to the fjords, but sweep round the coast on either side, and even appear on the islands that flank the mainland of Norway, some of them actually looking out to the open sea. The supposed ice-sheet must therefore have lain mainly outside these islands. But there is absolutely no evidence of any such detached western ice-body, and every reason to believe that it never existed.

At the period of maximum glaciation the ice-sheet probably advanced westward beyond the present limits of the land. But, when it began to retreat, it would naturally creep backward up the fjords, which would be still the main lines of ice-drainage. We can conceive, indeed, that at an early stage of this retreat, a glacier or ice-lobe may here and there have blocked up a large valley and produced a lake, as in the instances cited by Prof. Suess from Greenland. But the strand-lines of western Norway are not exceptional phenomena. They continue as characteristic features of the coast-line and of the fjords for several hundred miles, and must owe their origin to some general and widely extending cause. That they are true sea-beaches, as has been generally believed, Sir Archibald Geikie had not the smallest doubt.

Fortunately, we possess in our own islands a body of evidence bearing on this question, not certainly as voluminous and impressive as that of Scandinavia, but having the compensating advantage of great simplicity and clearness. On the one hand, the famous Parallel Roads of Glen Spean and Glen Roy, and those of other less known valleys, stand out as acknowledged relics of glacier-lakes; while round our coasts, on both sides of the country, raised beaches, which have been hitherto regarded as old sea-margins, run for hundreds of miles. These two series of terraces are found close together, yet there is no difficulty in drawing a satisfactory distinction between them. Indeed, their proximity enables us all the more clearly to perceive their contrasts.

There must, of course, be certain general resemblances between the littoral formations of lakes and of the sea. The erosion produced by the waves or wavelets of a body of fresh water is similar in kind to that performed by the sea, although different in degree. In like manner, the beaches of deposit formed in lakes possess, on a minor scale, many of the characters of those accumulated along the seashore. And it may readily be granted that, in isolated exposures of some old beach, it may be difficult or impossible to decide, in default of evidence from elsewhere, whether the phenomena observable are to be assigned to the work

of the sea or of a lake. Nevertheless, on a review of the whole evidence, at least as it is presented in this country, Sir Archibald felt very confident that there is no risk of confusion in this matter. The marine terraces maintain their distinctive features up to the very foot of the slopes where the lake terraces begin, while those in turn are marked by other special peculiarities.

Let any observer who has followed the great 50-foot raised beach along the western coast of Scotland and up the Linnhe Loch to the mouth of the Great Glen, look away to the right hand where the wide Strath of Spean leads into the interior. While yet standing on the platform of the raised beach, if the air be clear, his eye may detect the beginning of a line, drawn as with a ruler, at the same height along the slopes on either side of the valley. This is the lowest of the three great Parallel Roads of Glen Roy, and runs at a height of 850 feet above the level of the sea. If he will now ascend into Glen Roy, where the three terraces are best seen, he will soon be struck by the distinctive differences between these old lake-margins and the raised beaches with which he has already made himself familiar. In the first place, he will remark their faintness as compared with the marine platforms of the coast. Though readily traceable from a distance in their horizontal continuity, they are in many places hardly discernible when one is actually standing upon them. A little examination soon reveals that each of them has been produced mainly by the arrest of sediment washed from the slopes above into the water of the vanished lake. Instructive illustrations of this process may often be observed along the sides of reservoirs which have been constructed in steep-sided valleys: there each prolonged halt of the water at a particular level is marked by a shelf of detritus which, blown in by wind and washed down the declivities by rain, is stopped when it enters the water, where it accumulates as a miniature beach.

Here and there, especially on more exposed projections of the hillsides, there has been a little cutting-back by the shore-waves or drifting ice-floes of the old lake in Glen Roy. Occasionally also, where a streamlet has entered the water, its arrested detritus has accumulated as a broad, flat delta or terrace. But it is manifest that, in such limited expanses of water, wind-waves could have had comparatively little erosive power. Nor can we imagine that, even if the water froze, its floe-ice could have had any potent influence in sawing into the rocks of the declivities, and producing seter or rock-shelves. Certainly throughout this wonderful assemblage of lake-shores, there is nothing for a moment to be compared to the incised platforms of rock so abundant as part of the raised beaches of the western coast of Scotland. We must remember also that the production of such ice-dammed lakes took place as a mere episode in the retreat of the ice. No means are available to determine what may have been the length of time during which the water stood at the level of any one of these Parallel Roads. We may probably infer, from the absence of well marked and continuous intervening shore-lines, that the shrinkage of the ice and the consequent lowering of the level of the water were somewhat rapid.

The Parallel Roads of Lochaber, although the most imposing, are not the only examples of the shore-lines of ancient glacier-lakes in this country. Another striking case is that of Strath Bran in Ross-shire, where the glaciers descending from the mountains on each side ponded back the drainage of the valley, and sent it across the present watershed of the country at a height of about 600 feet above the sea. The conspicuous gravel-terraces at Achnashean are a memorial of this vanished sheet of water.

Now, with these undoubted records of ancient lakes, let us compare the structure and distribution of our Raised Beaches. These shore-lines are found, on both sides of Scotland, at approximately the same heights above the level of the sea. They are partly terraces of deposit, and partly true seter or platforms cut out of the solid rock, the same beach presenting frequent alternations of both structures. In general, it may be said that the detrital terraces are found chiefly in bays, sea-lochs, or other sheltered places, while the rock-terraces are conspicuous in more open sounds and exposed parts of the coast, where the tidal currents and wind-waves are most powerful.

As the highest terraces are the oldest, they have been longest exposed to the influences of denudation, and are thus the faintest and most fragmentary. But the dimensions and perfection of a raised beach do not depend merely on age, but in large measure on the length of time that the water stood at that level, and the varying local conditions that favoured or retarded the planing-down of solid rock or the deposition of littoral sediment.

That these beaches unquestionably mark shore-lines of the sea may be inferred on three grounds:—(1) Their position on both sides of the island at corresponding heights. No possible arrangement of ice-dams in the Atlantic and in the basin of the North Sea can be conceived that would have everywhere ponded back the land-drainage to similar levels. (2) Their independence of local conditions. The same terrace may be traced down both sides of a sea-loch and round the coast into the next loch, retaining all the while its horizontal continuity. Not only on the mainland, but on the chain of islands outside, the same parallel bar has been incised, both on the inner or sheltered side and also on the outer flank looking to the open Atlantic. (3) Their organic remains. From the youngest of the beaches up to the highest, the terraces of deposit contain marine organisms which have not been scooped out of some earlier formation, but lie in the positions in which the animals died, or into which they were washed by shore-waves and currents. The fossils of the latest beaches are entirely identical, or almost so, with forms still living in the adjacent seas, while those of the higher beaches are boreal or Arctic.

In some sheltered places, such as the Dornoch Firth, especially near Tain, and some inlets on the west side of the island of Jura, a number of successive bars or terraces of deposit may be observed up to heights of 100 feet or more above the sea. But there are in Scotland three strand-lines so conspicuous and so persistent that attention may be confined to them. From what has been taken to be their average height above mean sea-level or Ordnance-datum, they are known respectively as the 100-foot, the 50-foot, and the 25-foot beaches.

The author here adverted to what he had long regarded as a reproach to the geologists of this country. No systematic effort has ever yet been made to determine accurately, by a series of careful levellings, the precise heights of these old shore-lines. We only know that, roughly speaking, a raised beach retains its level for long distances, and appears to lie at the same height on both sides of the country. But we are still ignorant whether or not an appreciable difference of level might not be detected between the western and the eastern development of the same beach, nor do we know whether it would not betray some variation in its height between its northern and southern limits. There seems to be a tendency for the levels of the beaches to rise slightly towards the head of an estuary or sea-loch. But whether this difference is more than can be accounted for by the ordinary elevation of the tidal wave as it ascends a narrowing inlet remains to be determined.

Obviously, until accurate information is obtained on all ascertainable differences of level in the system of our raised beaches, we must remain unprovided with some of the most important material for a discussion of the history of these beaches. It is surely not too much to hope that one or more observers, endowed with the requisite geological knowledge and geodetic skill, may before long be found who will undertake the investigation of this interesting subject, and thus aid in the solution of a problem which does not merely concern the evolution of our own islands, but is of high importance as a question in geological theory.

The 100-foot, 50-foot and 25-foot beaches of Scotland were briefly described, and it was pointed out that in the structure of these old sea-margins a feature of special interest is presented by the platforms which have been eroded out of the solid rock, and which afford not a little light as to the origin of the Norwegian seter. The surface of these rock-terraces is flat, and usually covered with a thin coating of grass-grown soil through which harder knobs and stacks of the underlying rock here and there protrude. At the inner margin of the terrace, the rocks rise into a cliff or steep bank, the base of which is frequently pierced with caves. That these caves were mainly due to erosion by moving water is abundantly evident in

the rounded and smoothed surfaces of their sides. Their floors are often rough with round shingle, which has undoubtedly been the material employed by nature in their excavation. No one who has made himself familiar with the rock-platforms which at the present day are in course of erosion by the sea along these same coasts can for a moment doubt that the rock-platforms of the raised beaches which, down to the minutest point, resemble them, have likewise been eroded by the waves of the sea.

That the daily oscillations of temperature invoked by Prof. Suess in explanation of the Norwegian seter have had their share in the erosion of these Scottish examples cannot be doubted. But this share is evidently feeble in amount now, although it may have been more considerable during the Glacial period. More potent as a contributory influence in the erosion of the older terraces was probably the action of floating ice, driven along the shores by winds and tidal currents. Down to the time of the 50-foot beach, when glaciers in the north of Scotland descended to the edge of the sea, there may have been a good deal of such ice in the more enclosed sea-lochs, where the water, freshened by the discharge of melting snow-fields and glaciers, might itself be covered with a cake of ice. And there was not improbably a good deal more ice in the fjords of Norway. The grinding and rasping action of such ice, driven by gales ashore, has long been remarked. But in any case we are justified in regarding the Scottish seter as examples of truly marine erosion, and there appears to be no reason why those of Norway should not have had the same origin. It is at least clear that the statement that the characters of seter "are absolutely irreconcilable with what we know of the action of the sea near its surface," cannot be sustained.

Certain features of the extension of the raised beaches throughout Britain appear to be of fundamental importance in relation to the discussion of the problem of the emergence of land. Though so persistent along both the western and eastern coasts of Scotland, these beaches, as is now well known, do not stretch northward into the Orkney and Shetland Isles. Along precipitous sea-fronts we could not expect to meet with them, but among these islands there are endless sheltered inlets and bays which, had they indented the shores of the mainland of Scotland, would undoubtedly have had their fringe of terraces. The conditions for the development and preservation of the beaches were so entirely favourable, that their absence can only be legitimately accounted for on the supposition that they can never have existed here. Still farther north, among the Færöe Isles, no trace of any raised beaches has been found among the numerous natural harbours and creeks that break the monotony of the vast ranges of basalt-precipice. Here, again, we cannot suppose that any such beaches were ever formed.

In the southward extension of the Scottish raised beaches these features begin to lose their distinctness as they are traced into England. The 100-foot beach, which has not been recognised along the northern coast of Sutherland or in Caithness, appears also to fail before it reaches the English coast. It is well marked in the estuaries of the Clyde and Forth, whence in a fragmentary condition it has been traced into Wigtonshire on the one side and to the north of Berwickshire on the other. But no remnants of it appear to have been detected in the North of England.

The raised beaches of the north and east of England were briefly referred to, and it was then shown that in England and Wales the most continuous and best preserved examples are to be seen on the coasts of the southern counties. The lower raised beaches along the coasts of Dorset, Devon and Cornwall have long been known, although their geological age, their history, and their relation to the later phases of Pleistocene time, have not yet been satisfactorily cleared up. William Pengelly, who devoted so much time to this subject, clearly proved that these beaches do not stand now at their original level, but that after their formation the region was upraised to the amount, as estimated by him, of not less than 70 feet, when the lowest sunk forests flourished as land-surfaces, and that thereafter came a submergence of certainly 40 and perhaps many more feet.

Mr. Tiddeman has shown that, in Gower, on the coast of Glamorgan, a raised beach which lies from 10 to 30 feet above the level of the modern beach, and contains littoral shells of common species, is yet older than at least some part of the Glacial period, for it is overlain by Glacial drift. In this case, also, its present is probably not its original level. There is evidence of considerable submergence, at a comparatively late period, farther east in the same county and along the southern coast of England, and the inter-Glacial or pre-Glacial raised beaches of the whole of this region doubtless stood at one time higher above the sea-level than they do now.

The raised beaches of Ireland were alluded to, special attention being directed to an ancient shore-line at Cork Harbour, which has recently been traced by Messrs. Muff and Wright, of the Geological Survey, not only within the harbour, but for a long distance on the shore to the east and west of that inlet. Though only a few feet above the present high-water mark, this beach has been ascertained to be older than the oldest Irish Boulder-clay, for it is overlain by the so-called "shelly marl" which was brought in upon the land from the sea-basin. The similarity of position and antiquity between this beach and that underlying the drift in Gower is obviously as important as it is interesting. A shore-line, which must be of pre-Glacial or inter-Glacial age, is traceable in the south of Ireland and in South Wales. It has not only survived the erosive processes of the Glacial period, but it appears to have outlived some serious alterations in the relative levels of sea and land, which have taken place since its formation. Moreover, we have to note the fact that neither at Cork nor in Gower does any younger post-Glacial terrace appear to be recognisable. If we might judge from the analogy of other parts of these islands where the succession of raised beaches is tolerably complete, we should infer that if ever any later terrace existed here it must now be submerged—an inference which, it will be observed, is supported by the evidence of considerable submergence in South Wales and on the southern coast of Hampshire.

(ii.) *Submergence.*—Of the various kinds of proof of the submersion of terrestrial surfaces furnished in these islands only two were dealt with: first, the extension of land-valleys beneath the sea, and, secondly, the existence of what are known as sunk forests.

(1) That the fjords of Norway, the sea-lochs of the west of Scotland, and the harbours or inlets of the west of Ireland were originally valleys on the dry land, although now deeply submerged, has long been an accepted belief among those geologists who have specially considered the subject. The interval of time which has elapsed since this submergence has not sufficed to fill up with sediment these submarine depressions. By a study of the sea-charts, we can still trace the winding curves of the ancient valleys, and can even here and there detect among them the basins which, when the present sea-bottom was a land-surface, were filled with fresh-water lakes. On the sea-floor to the east of our own country and of Scandinavia, such relics of subaërial denudation are less imposingly preserved, yet evidence of the submergence of land-valleys has been noted there also. It must of course be remembered that the land on that side is of much lower altitude than on the western coasts, that the ground slopes gently under the sea, and that the valleys are comparatively insignificant depressions on its general surface. Moreover, the more abundant drainage on the longer slope east of the watershed, and the much greater development of drift on that side, leads to a far more copious discharge of sediment into the shallow North Sea and the Gulf of Bothnia, and the submarine prolongations of the old land-valleys are thus apt to be buried under recent accumulations of detritus. There may, however, perhaps be another cause for the contrast between the profoundly indented and precipitous western coast and the comparatively low and monotonous trend of the eastern coast. The author had long been disposed to believe that the submergence has been greater towards the west than towards the east. In the prolongation of the West Highland sea-lochs on the floor of the Atlantic outside, the original land-surface sometimes lies 600 feet or more below the present sea-level. If the submerged land-surface of north-western Europe could be upraised some 600 feet, the submarine prolongations of the sea-lochs would once more become glens and straths, and their rock-basins would again be turned into fresh-water lakes.

There is no similar series of well marked submerged valleys on the floor of the North Sea from which to estimate the amount of submergence of that tract, at least half of which, at no very distant date, formed a land-surface that connected Britain with the rest of the Continent. The charts show this sea-floor to consist of two distinct portions. The northern half forms a plain, which appears to slope gradually towards the north. The southern half, however, rises somewhat rapidly from the edge of that plain into an escarpment that runs in a north-easterly direction for a distance of 500 miles, from off Flamborough Head to the Skagerrak. From the top of this escarpment the surface undulates southward as a higher submarine plain, traversed by the still feebly traceable submerged valleys of the Elbe, the Rhine, and the Thames, and covering an area of more than 50,000 square miles. An uprise of not more than 300 feet would turn this tract into a rolling plateau of dry land, like the downs and wolds of Yorkshire, which are its emerged continuation. Such an amount of uplift would probably be amply sufficient for the transaction of all the later geological history of the region. The conversion of the area into a sea-bottom may not have been a continuous process. It was probably in operation during the early stages of the Glacial period, and its latest phases come down at least into Neolithic time.

(2) The sheets of peat with stools and trunks of trees, known as sunk or submerged forests, and of such frequent occurrence around the coasts of the British Isles, have long been confidently regarded as proofs of recent subsidence of the land. That they generally mark former land-surfaces cannot be doubted, for the tree stumps are seen to send their roots down into the soil underneath, and manifestly stand in the places where they originally grew. The presence of hazel-nuts, elytra of beetles, land-snails, and other terrestrial organisms, affords further confirmation of this conclusion. The great majority of these vegetable accumulations are found between tide-marks in bays and estuaries, and in many cases they can be seen to pass below the limits of the lowest tides, and thus to be constantly in part submerged. The trees and the fresh-water plants must have lived above the reach of the sea, so that they now lie 20 feet or more below the level at which they originally grew, and the conclusion has been drawn that they mark a general subsidence of these islands, to the amount of at least 20 feet, at a comparatively recent date.

Sir Archibald Geikie was inclined to believe that this conclusion has been rather too sweepingly drawn. That some of the submerged forests may be satisfactorily accounted for without any change in the level of the land or of the sea was urgently enforced more than eighty years ago by John Fleming, in reference to the examples first brought to notice by him in the estuaries of the Tay and the Forth. It will be readily understood that, in the later stages of the Glacial period, when much detritus was swept off the land into the sea, the conditions would probably be especially favourable for the formation of alluvial bars along our coasts, such as are now in course of accumulation for hundreds of miles on the southern coast of Iceland, where some of the features of that period may still be said to linger. Behind these barriers lagoons would arise, which in course of time might become marshes, and eventually peaty flats, supporting a growth of trees. But when the supply of sediment failed, and the sea, instead of heaping up the bars, began to breach them, the level of the bogs would sink by the escape of their water to the beach, and the tide at high-water would overflow and kill off the forests. Occasionally, owing to the action of underground drainage, the seaward margins of forest-covered peaty flats may have been detached from the main body and launched downward on the beach, even beneath low-water mark.

Had our littoral sunk forests been confined to a few places where the topographical conditions were specially favourable for their production, we may concede that they would not in themselves furnish sufficient proof of a shift of level, either on the part of the land or of the sea. But when we consider their widespread distribution all round the margin of these islands, even on those shores where it is difficult to believe that there has been any subsidence or slipping downward of a land-surface owing to the draining off of underground water, we may well doubt whether the old belief should be disturbed, that the facts, taken as a whole, prove a general submergence.

Fortunately, the evidence available on this subject allows us to go a step farther. We need not be content with such debateable proofs as are furnished by the sunk forests between tide-marks, for land-surfaces can be adduced which are buried beneath marine accumulations in circumstances that leave no doubt as to the facts of submergence.

The author, after presenting some details proving submergence at Belfast, at Hull, and at Grimsby, to the extent of sometimes as much as 52 feet, stated that on the coast of South Wales interesting sections had been laid open in the excavation for the Barry Docks, in Glamorgan, furnishing conclusive proof of a succession of at least four layers of peat overlain by estuarine deposits, and in a situation which precludes any recourse to local settlement by drainage of underground water or downward slipping. The strata are manifestly undisturbed, and the lowest is an unmistakable land-surface. It consists of peat full of remains of oak, hazel, cornel, hawthorn, and willow, together with crushed shells of Hyalinia and, apparently, Pisidium and Planorbis. The soil underneath this forest-growth has yielded specimens of Helix, Hyalinia, Succinea, Limnæa, Pupa, and Valvata. This buried forest-growth lies at a depth of 35 feet beneath Ordnance-datum, or 55 feet beneath the line of high-water of ordinary spring tides. It proves a submergence of at least 55 feet, and the peat-bands at higher levels mark successive pauses in this submergence. That the movement was in progress in Neolithic time may be concluded from the occurrence of a portion of a polished celt in the uppermost layer of peat, from which also two bone needles are reported to have been obtained. Mr. Strahan informed the author that, wherever excavations have been made at the mouths of the valleys on the coast of South Wales, similar layers of peat have been cut through at depths below low-water mark. It would thus appear that the submergence has been general all along the coast-line.

On the southern English coast similar evidence of a considerable change of level has long been known. During the extensive excavations for new dock accommodation at Southampton, a bed of peat, 10 feet thick, has been found, descending to a depth of 43 feet below Ordnance-datum. This vegetable accumulation has yielded many land and fresh-water shells; abundant trunks of oak with roots, sometimes 2 feet long, passing down into the loam beneath; plentiful remains of beech and hazel, together with some birch and pine. The plants also include bulrush, sedge, bog-myrtle, heaths, and bracken. From this bed, bones, horn-cores, and part of the skull of *Bos primigenius* were obtained; likewise horns and bones of red deer, tusk of boar, bones of hare, and horn of reindeer. Traces of man were found in the same deposit, as shown by the occurrence of dark flint-flakes, a round perforated hammer-stone, and a fine bone needle polished by use.

There is thus evidence of a comparatively recent submergence of the south-west of England to the extent of at least 50 or 60 feet. We are probably justified in considering the present position of the Glacial raised beach in Gower as a further indication of the same movement, and there seems no reason why we should not connect the evidence of this beach with that of the terrace lately detected in Cork. If these tracts are included in our survey, we see that the submergence probably stretched across South Wales and St. George's Channel to the south of Ireland. The evidence from Hull and Grimsby, which shows that a similar marked submergence has taken place along part of the east coast, not improbably indicates that the change of level extended across Wales and the centre of England. This submergence appears to be the latest in the long series of oscillations which have affected the southern portions of our islands. No proof has yet been obtained that so serious an amount of recent submergence has extended farther north. In the northern tracts the latest recorded change of level has been an emergence of the land in Neolithic time.

(iii.) *Bearing of the Evidence on the Causes of Emergence and Submergence.*—In conclusion, the author pointed out the inferences that appeared to him to be deducible from the

evidence obtainable in the British Isles, in regard to the causes which, in this region, have determined the emergence and submergence of land. The vertical range of the changes of level to which the discussion in this address was limited amounts at least to as much as 700 feet, that is, some 600 feet below and 100 feet above the surface of the sea. But it will be remembered that, if we include all the deposits that contain recent marine shells *in situ*, the range of movement will be found considerably to exceed 1000 feet. The problem to be solved is whether this wide amplitude of shift in the relative levels of sea and land should be attributed to variations in the height of the surface of the oceanic envelope, or to secular movements of the terrestrial crust.

Any change of sea-level might be expected to be general and fairly uniform over long distances. The area of the British Isles is too restricted to permit us to believe that there could ever have been any serious difference in sea-level between the eastern and western coasts, or between the northern and southern limits of the country. Whether, therefore, the surface of the sea rose upon the land or sank away from it, we should find the records of these changes to extend over the entire region, and to be marked on the whole by a persistent uniformity of level. But an examination of the evidence fails to furnish proofs of any such extension and uniformity.

In the first place, the raised beaches, although so perfectly developed over nearly the whole of Scotland, disappear towards the north among the Orkney and Shetland Islands where, had they ever existed, they had every chance of being as well preserved as anywhere on the mainland. These islands obviously lay outside of the area affected by the movement that led to the formation of the beaches. But they could not have escaped from the effects of any rise in the level of the sea. Again, it is incredible that if the great 100-foot terrace, so prominent a feature in Scotland, had been formed by an uprise of the surface of the sea, the same terrace should not have been visible in thousands of favourable positions in England, Wales, and Ireland. Its entire absence cannot be accounted for by the presence of former ice-sheets in these regions, or by subsequent denudation. This absence may surely be taken as proof that the terrace never extended over these parts of our islands.

In the second place, had the position of the buried forests in the southern half of England and Wales been due to a rise in the sea-level, similar evidence of submerged land-surfaces at corresponding depths should have been met with generally round our coast-line. Neolithic man was an inhabitant of the country before this submergence was complete, and has dropped his handiwork in the beds of peat. In the north of Ireland and in central Scotland, however, during Neolithic time the land was emerging from the sea, and man has left his flint-flakes and weapons in the youngest raised beaches. Thus in the same period of geological time the sea-level must be supposed to have risen 50 or 60 feet in the south, and to have sunk 25 or 30 feet in the north. But we cannot suppose that within a distance of 300 or 400 miles there could have been a difference of 75 feet or more in the level of the water.

In the third place, there can be little doubt that when accurate levellings are taken of the raised beaches, it will be found that their apparent horizontality is not absolute, but that they rise slowly in certain directions, more particularly towards the axis of the country. It is not improbable also that a difference of level will be detected between the same beach on the eastern and on the western coast, and between its most northerly and most southerly parts. Such evidence of a deformation of the land can only be determined by careful geodetic measurements still to be undertaken.

In the meantime, on a review of the whole evidence, the author felt confident that the balance of proof is largely in favour of the old belief that the changes of level, of which our islands furnish such signal illustrations, have been primarily due, not to any oscillations of the surface of the ocean, but to movements of the terrestrial crust connected with the slow cooling and contraction of our globe. If this belief is to be overthrown, better evidence must be brought against it than has been hitherto adduced.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—On Saturday, May 28, the following honorary degrees were conferred on foreign delegates of the International Association of Academies:—D.C.L., Chevalier Edouard Descamps (of the University of Louvain), Ministre d'État, Sénateur Belge. D.Litt., J. L. Heiberg, University of Copenhagen; M. Émile Senart, Académie des Inscriptions et Belles-Lettres, Paris; M. Boutroux, Académie des Sciences Morales et Politiques, Paris; Prof. Collignon, Académie des Inscriptions et Belles-Lettres, Paris. D.Sc., Prof. Dr. Flechsig (Leipzig), Kgl. Sächsische Ges. der Wissenschaften; Prof. E. Ehlers, Kgl. Ges. der Wissenschaften, Göttingen; M. A. Giard, Académie des Sciences, Paris; Dr. Victor von Lang, Kaiserl. Akad. der Wissenschaften, Vienna; Prof. H. Mohn, chairman of the committee of the Videnskabs Selskab, Christiania; and Prof. H. Obersteiner, of the University of Vienna.

A meeting of the Junior Scientific Club was held on May 27. Papers were read by Mr. R. T. Lattey, on "Electrochemical Actinometers," and by Mr. E. C. Atkinson, on "Surveying in South Africa."

The following are among the honorary degrees to be conferred at the Encænia on June 22:—D.C.L., Mr. Charles Booth, F.R.S., president of the Royal Statistical Society. D.Sc., the Hon. C. A. Parsons, F.R.S.; Prof. Pierre Curie; Sir W. S. Church; Sir Andrew Noble, F.R.S.; Sir William Crookes, F.R.S.; Sir David Gill, F.R.S.; Sir John Murray, F.R.S.; Prof. Alfred Marshall; Prof. J. J. Thomson, F.R.S.; Prof. Horace Lamb, F.R.S.; Prof. A. R. Forsyth, F.R.S.; Prof. Dewar, F.R.S.; and Prof. Larmor, Sec.R.S.

CAMBRIDGE.—The following are the speeches delivered by the Public Orator, Dr. Sandys, on May 28, in presenting the under-mentioned members of foreign academies for the degree of Doctor in Science, *honoris causâ*:—

PROF. BAKHUYZEN, OF LEYDEN.

Inter doctores nostros novos primus hodie progreditur Scientiarum Academiae Amstelodamensis praeses, Batavorum astronomus insignis. Abhinc annos septemdecim consilii magni inter auctores fuit, quo caeli totius stellae, luminis ipsius auxilio chartis impressae, accuratissime redderentur. Etiam altero in opere immenso cum aliis consociatus est, quo caeli parte Boreali in regiones sedecim divisa, stellarum multitudo infinita minutissime observaretur. Iuvat hodie recordari caeli regionem astronomo Leidensi assignatam regioni Cantabrigiensi esse conterminam. Idem latitudinis (ut aiunt) varietatem, orbis terrarum axe leviter vacillante exortam, diligenter exploravit. Talium virorum ope Europae gentes scientiae amore excitatae, etiam in orbe terrarum accuratius dimetiendo invicem certant, astronomi illius antiqui laudem aemulatae,

"descripsit radio totum qui gentibus orbem."

PROF. FAMINTSYN, OF ST. PETERSBURG.

Russorum ab imperio adest botanicae professor eximius, qui studiorum provinciam nactus pulcherrimam, rerum omnium, quas terra gignit, physiologiam inter primos exploravit. Quam exquisitis usus experimentis, ostendit artificio quam admirabili herbarum genus omne solis radiis tactum virescat; etiam subter aquas algae minutissimae motu tremulo vibrent; foliorum denique omnium in cellis primordia quaedam viriditatis sese explicent, sed eadem solem nimium reformident. Quam feliciter idem novo lumine rem obscuram illustravit, vitamque illam communem, quae inter animalia quaedam minutissima et algarum cellulas intercedit, diei in lucem nuper protraxit.

"sic unumquicquid paulatim protrahit aetas
in medium, ratioque in luminis erigit oras."

EDMUND MOJSISOVICS, EDLER VON MOJSVÁR, OF VIENNA.

Vindobonensium ab Academia insigni ad nos advectus est vir de geologia praeclare meritus, qui duodequadraginta per annos palaeontologiae studiis deditus, Ammonis praesertim cornua, rupium in sinu insculpta, aevi prioris indicia (prope dixerim oracula) verissima existimavit. Quid dicam

de montium Dolomitorum serie et in Rhaetia et prope Venetos ab eodem dilucide descripta? quid de ratione illa quam inter Europae atque Asiae montes maximos intercedere indicavit? Oceanum certe ingentem, quem ex mari Mediterraneo ad oceanum Pacificum quondam extendere magister eius probavit, argumentis novis revera exstitisse discipulus confirmavit, ultraque Atlantida quandam, etiam maris "Arcto-Pacifici" fines antiquos determinavit. Nemo mortalium fortasse Oceanorum antiquorum amplitudines metiri audacius conatus est, nemo tot Alpium ingentium varietates accuratius inter sese comparare.

EMERITUS PROF. RETZIUS, OF STOCKHOLM.

Scandinavia, cuius etiam Regem inter doctores nostros numeramus, auspiciis optimis ad nos misit anthropologiae physicae conditoris insignis filium illustrem, qui anatomiam olim praeclare professus, eidem scientiae etiam otium suum et annos emeritos destinavit. Peritis nota sunt volumina illa maxima, eademque et typorum et imaginum splendore pulcherrima, et cerebri ipsius et sensuum omnium anatomiae et physiologiae explicandae dedicata. Idem, patriae non immemor, etiam Scandinaviae priscae "crania antiqua," arte eximia depicta, in libro singulari ordinavit. O terram felicem, quae non modo regia in domo artium et scientiarum tot cultores, tot patronos, numerat, sed etiam inter professores suos virum munificentia prope regia insignem non immerito admiratur.

PROF. RIECKE, OF GÖTTINGEN.

Academiae Goettingensis, et regiae domus Hanoverianae vinculo antiquo et hospitii iure vetere nobis coniunctae, socium eximium salutamus, qui scientiae physicae provincias multas peragravit; qui et de vi electrica cum crystallis consociata, et de corpusculis illis electricis inter nosmet ipsos primum indicatis, non minus breviter quam dilucide disputavit; qui denique, in scientiae illius experimentis libro in unico explicandis, inter tot res minutissimas ab alio aut alio observatas, rationem ipsam ubique eminere et apparere passus est. Illa vero rerum omnium domina est; illa nos praesertim et in scientiarum inventis praeteritis delectat et spe maioris in posterum incrementi excitat. Etenim de studiis ad lucis leges pertinentibus, non minus quam de ipsa luce, poëtae antiqui verba illa vera sunt:

"suppeditatur enim confestim lumine lumen
et quasi protelo stimulatur fulgere fulgur."

PROF. WALDEYER, OF BERLIN.

Academiam Berolinensem, et in scientiis et in litteris celeberrimam, oculis nostris quasi praesentem hodie reddit vir eximius, Academiae ipsius in scientiis physicis et mathematicis alter e ministris praecipuis, qui anatomiae in provinciis plurimis plurima cum laude versatus, vitae nascentis praesertim e studiis famam singularem est adeptus. Neque vitae ipsius circa limina obscura moratus, etiam urbium magnarum in lucem progressus est. Is certe, qui morum urbanitate et sermonis eloquentia anatomiae professores illos antiquos, Herophilos et Erasistratos, sine dubio superavit, est profecto, velut alter Hippocrates medicinae pater a Celso laudatus, "vir et arte et facundia insignis."

THE honorary degree of Doctor in Letters was conferred upon the Comte de Franqueville, sometime president of the Institute of France; Prof. Goldziher, member of the Hungarian Academy of Sciences and professor of Semitic philology in the University of Budapest; Prof. Gomperz, Emeritus professor of classical philology in the University of Vienna; Prof. Krumbacher, member of the Royal Bavarian Academy of Sciences and professor of mediæval and modern Greek philology in the University of Munich; M. Paul Leroy Beaulieu, of the Institute of France; and M. Georges Perrot, member of the Institute of France.

MR. W. GARDINER, F.R.S., Clare, Prof. C. S. Sherrington, F.R.S., Caius, and Mr. G. T. Walker, F.R.S., Trinity, have been approved for the degree of Doctor of Science.

The John Lucas Walker studentship in pathology, value 200*l.* a year for three years, will be vacant at Michaelmas. Applications are to be sent to Prof. Sims Woodhead before June 27. The student need not be a member of the university.

It is proposed to appoint a demonstrator of surgery, a demonstrator of experimental psychology, and an assistant curator of the museum of botany.

Sixty-seven men and twenty-two women have acquitted themselves so as to deserve honours in the mathematic tripos. The class list will be published on June 14.

A "NATURE STUDY" museum at St. George's Recreation Ground, Cable Street, E., will be opened to-morrow, June 3, at 5 p.m., by Sir William J. Collins, chairman of the Education Committee of the London County Council.

THE governing body of the Northampton Institute has decided to establish day classes in technical optics at the institute next winter. These courses will include full time courses, in which students will attend about thirty hours per week, and also morning classes for two mornings per week for those already engaged in the industry. An appeal is being made to members of the optical trade for donations towards the support of these technical classes with a view to the establishment and maintenance of British supremacy in the optical industry. It is reported that the London Education Committee will proceed shortly to consider the establishment of a central optical institute or college, and it is probable the decision arrived at will depend largely upon the attitude of the optical trade towards classes such as those at the Northampton Institute.

A REPORT prepared by the preliminary scientific education and examination committee of the General Medical Council was considered at the meeting of the council on Friday last, and the following resolutions were passed:—(1) That an examination in chemistry, in order to be sufficient, should comprise a written paper, a practical examination, and an oral examination; (2) that, in respect of chemistry, a synopsis or syllabus of subjects should be issued by each licensing body, and that the scope of the examination in chemistry should not fall below that which has been indicated in the report of the visitors, and has been generally approved by the licensing bodies; (3) that the examination in practical chemistry should not be limited to simple qualitative analysis, but should include easy preparations, simple volumetric analysis, and simple experiments illustrating important principles; (4) that an examination in physics, in order to be sufficient, should comprise a written paper and an oral examination, the latter to include practical questions on the use of physical instruments and apparatus; (5) that, in respect of physics, a synopsis or syllabus of subjects should be issued by each licensing body, and should include the elementary mechanics of solids and fluids and the rudiments of heat, light, and electricity; (6) that elementary biology should be retained in the curriculum; (7) that an examination in elementary biology, in order to be sufficient, should comprise a written paper and an oral examination, the latter to include practical questions on specimens and dissections, and on methods of microscopical investigation; and (8) that, in respect of elementary biology, a synopsis of subjects should be issued by each licensing body.

THE "Code of Regulations for Public Elementary Schools" for 1904 has been issued by the Board of Education. It has been much simplified, both in phraseology and arrangement. In the place of detailed schemes of work in a multitude of subjects suitable for the seven standards of an elementary school, the Board has sketched in broad outline a graduated course of instruction on which the education given in every public elementary school should be based. In this course of instruction a prominent place is given rightly to a "knowledge of the common phenomena of the external world, with special reference to the formation of a habit of intelligent and accurate observation, and to the application of that habit—in conjunction with simple forms of experiment—in the daily life and surroundings of the scholars." Nor is this the only opportunity taken by the Board, in this important official document, to show clearly its belief in the value and essential nature of scientific work in all schemes of education. An introduction to the code defines the purpose of an elementary school education as being "to form and strengthen the character and to develop the intelligence of the children." The introduction continues later to say that "with this purpose in

view it will be the aim of the school to train the children carefully in habits of observation and clear reasoning, so that they may gain an intelligent acquaintance with some of the facts and laws of nature." The importance of practical work and manual instruction is duly emphasised. This recognition of the claims of natural knowledge to an honoured place in the work of our primary schools will go far to reward men of science for their efforts to convince educational authorities of the value of scientific training. It is to be hoped that elementary school teachers will take full advantage of their new charter, and show by the improvement of their work that they value their new freedom to educate on rational lines.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 5.—"On certain Physical and Chemical Properties of Solutions of Chloroform in Water, Saline, Serum, and Hæmoglobin. A Contribution to the Chemistry of Anæsthesia.—(Preliminary Communication.)" By Benjamin **Moore,** M.A., D.Sc., Johnston Professor of Bio-chemistry, University of Liverpool, and Herbert E. **Roaf,** M.B., Toronto, Johnston Colonial Fellow, University of Liverpool.

Summary and Conclusions.

(1) It is believed that the experiments recorded in this paper justify the conclusion that chloroform forms an unstable chemical compound or physical aggregation with the proteids experimented with, and that it is carried in the blood in such a state of combination. Since proteids build up the protoplasm of living cells, it appears to us probable that chloroform, and other anæsthetics, must form similar combinations with protoplasm, and that anæsthesia is due to the formation of such compounds which limit the chemical activities of the protoplasm. The compounds are unstable, and remain formed only so long as the pressure of the anæsthetic in the solution is maintained. Such compounds are formed not only by hæmoglobin, but by serum proteid, and hence the position taken by the anæsthetic in hæmoglobin is not that of the respiratory oxygen. This is further shown by the fact that the oxygen-carrying power of hæmoglobin is not interfered with in presence of chloroform.

The effect of chloroform upon various forms of protoplasm will form the subject of future experiments.

The facts upon which we rely as proofs of the formation of a compound or aggregation between chloroform and serum proteid or hæmoglobin may be summarised as follows:—

(*a*) Chloroform has a much higher solubility in serum or hæmoglobin solutions than in saline or water.

(*b*) *Even in dilute solutions* at the same pressure the amount of chloroform dissolved in serum or hæmoglobin solution is considerably higher than in saline or water.

(*c*) The curve of pressures and concentrations in the case of water and saline is a straight line, while in the case of serum and hæmoglobin solution it is a curve, showing association at the higher pressures.

(*d*) In the case of serum, chloroform causes a marked opalescence, and also a slow precipitation at room temperature (15° C.), and at body temperature (40° C.) a rapid, though incomplete precipitation. In the case of hæmoglobin, 1·5 to 2 per cent. of chloroform causes a change of colour and commencing precipitation at room temperature, which becomes almost complete in the thermostat at 40° C., while 5 per cent. and over causes complete precipitation even at 0° C.

(2) The relations between chloroform pressure and concentration in solution have been worked out throughout a long range, from below the anæsthetising values (8 to 10 mm.) to nearly saturation in the case of water, saline, and serum.

Attention may be directed here to the important practical fact that with the same percentage of chloroform in the air breathed, serum or hæmoglobin, and therefore the blood will take up much more chloroform than would water or saline under equal conditions. Thus at the anæsthetising pressure, and at 40° C., the coefficient of distribution in the case of water and saline is approximately 4·6, while that of serum is 7·3; at room temperature (15° C.) these coefficients become 8·8 and 17·3 respectively.

"Note on the Lymphatic Glands in Sleeping Sickness." By Captain E. D. W. **Greig,** I.M.S., and Lieut. A. C. H. **Gray,** R.A.M.C.

The authors have examined the contents of lymphatic glands during life from fifteen sleeping sickness patients. In all of them actively motile trypanosomes were very readily found in cover-glass preparations taken from the cervical glands. They were also present in other glands, such as the femoral, but were not nearly so numerous.

The authors consider that their observations throw a new light upon the glandular enlargements which have been so constantly noticed in sleeping sickness, and that the disease is essentially a polyadenitis brought about by the arrest of the trypanosomes in the glands where many of them are destroyed, but whence some escape from time to time into the blood stream and thus occasion the increase which has been observed in the peripheral circulation.

They regard their observations upon the presence of trypanosomes in number in the lymphatic glands of both early cases of trypanosomiasis and advanced cases of sleeping sickness as affording important evidence of the unity of these diseases, and further proof that the trypanosomes are the essential cause of sleeping sickness.

"A Note on the Action of Radium on Micro-organisms." By Dr. Alan B. **Green.** Communicated by Sir Michael Foster, K.C.B., F.R.S.

The radium salt used in these experiments was 1 centigram of practically pure radium bromide, contained in a vulcanite and brass capsule fronted with thin talc. The emanations applied to micro-organisms were the β and γ rays.

(1) In the first set of experiments the germicidal action of these rays on various species of bacteria was investigated. A mass of bacteria was placed, as a thin layer, in a hollow-ground glass slide, and the capsule containing the radium was placed over the mass in such a way that the radium was brought within 1–2 mm. of it. All experiments and controls were made at room temperature.

It was found that the specific germ of vaccinia was killed by an exposure to radium of 22 hours or less. Non-spore-bearing bacteria were killed generally by 2 to 14 hours' exposure to radium, while spores were not killed by less than three days' exposure. It was further found that (*a*) as the distance between the radium and the bacteria was increased germicidal action became less evident and finally ceased; (*b*) as increased thicknesses of lead were interposed between the radium and the bacteria, *i.e.* as the β rays were cut off, germicidal action became less and less evident.

(2) It was ascertained that after exposure to radium at a distance of 1–2 mm. for 24 to 120 hours, micro-organisms themselves became radio-active. It has not yet been ascertained whether living micro-organisms can exhibit induced radio-activity, but micro-organisms killed by radium emanations show this activity. No radio-activity was found in bacteria not previously exposed to radium. The induced radio-activity of bacteria was shown by the ability of a mass, after exposure to radium, to photograph itself when brought into apposition with the film of a sensitised photographic plate. The best photographs so far have been obtained from cultures containing spores. Radio-active organisms have given off photo-actinic emanations after three months have elapsed since their exposure to radium. Photographs of such bacterial masses have been obtained through a double layer of lead foil, but as the β rays were cut off by interposing greater thicknesses of lead the passage of photo-actinic rays to the sensitised film was prevented.

"Further Note on some Additional Points in Connection with Chloroformed Calf Vaccine." By Dr. Alan B. **Green.** Communicated by Dr. W. H. Power, C.B., F.R.S.

Since a former paper on this subject was read in April, 1903, the use within two weeks of their collection from the calf of a large number of vaccine lymphs prepared by the chloroform process has resulted in high "case" and "insertion" success.

The following further points in connection with these vaccines have been investigated:—

(1) The temperature at which vaccine water emulsion is

subjected to the chloroform process determines largely the rate at which the extraneous bacteria of that emulsion are eliminated. The temperature at which extraneous bacteria are killed most quickly, the specific germ being left meanwhile in a state of full activity, lies probably between 18° C. and 23° C.

(2) It has been found that several additional species of bacteria are rapidly eliminated from vaccine by means of the chloroform process:—*B. proteus vulgaris*, *B. prodigiosus*, *B. pyocyaneus*, *B. fluorescens liquefaciens*, *B. coli communis*, *B. typhosus*, *B. diphtheriae*, *B. mallei*, *B. pestis*, *B. tuberculosis* and *S. cholerae Asiaticae*. These bacteria were added artificially to vaccine collected for experiment only.

(3) The keeping properties of chloroformed vaccine have been investigated. Vaccines prepared by the chloroform process were stored for the same length of time as commonly elapses at these laboratories between the collection from the calf and use of lymphs prepared by glycerination—usually six weeks. The use of these stored chloroformed lymphs was attended with results of high "case" and "insertion" success.

Thus the further use of a large number of chloroformed vaccines confirms the conclusions arrived at in a former paper, and the important additional knowledge has been gained that chloroformed vaccine, if originally of sufficiently high potency, will, when prepared and stored under suitable conditions, retain potency in a high degree for a considerable time.

Linnean Society, May 5.—Prof. S. H. Vines, F.R.S., president, in the chair.—Colour and coloration in mammals and birds: J. L. **Bonhote.** In this the author brought forward further facts in support of the theory that the colour and coloration on animals are primarily due to physiological causes, and showing that where conditions of "high vigour" existed, the animals were as a rule deeply coloured. The second part of the paper dealt with the coloration, and examples were brought forward showing that before a moult the hair bleached along certain definite areas, and also that this bleaching was not a process continuing throughout the period between the moults, but confined as a rule to a few days or weeks immediately preceding the moult. Hence it was argued that both colour and coloration were primarily due to physiological causes, and that natural selection could only make use of those markings which were in the first place due to "vigour."—The cranial osteology of the fishes of the families Mormyridæ, Notopteridæ, and Hyodontidæ: Dr. **Ridewood.** Descriptions were given of the skulls of *Mormyrops deliciosus*, *Petrocephalus bane*, *Notopterus kapirat* and *Hyodon alosoides*, together with less complete accounts of those of Marcusenius, Gnathostomus, Hyperopisus, Mormyrus and Gymnarchus. As the result of a study of the skulls of these forms, Dr. Ridewood concludes that the families Mormyridæ, Notopteridæ and Hyodontidæ, though more closely related *inter se* than is either family with any other family of malacopterygian fishes, are not more intimately related with one another than was previously assumed to be the case.

Faraday Society, May 9.—Mr. Bertram Blount in the chair.—Studies in viscosity: Dr. C. E. **Fawsitt.** The paper referred to some relations of viscosity to salt formation and viscosity as an additive property.—The electrolytic oxidation of anthracine: Dr. F. M. **Perkin** and A. **Fontana.** The authors have taken up the study of the oxidation of anthracine primarily to ascertain whether it was possible to obtain a good laboratory method for the preparation of anthraquinone. The first attempts were made with solutions in acetone, platinum electrodes being employed. Although oxidation took place in solutions of anthracine in acetone, it was not found possible to oxidise more than about 55 per cent. of the anthracine. Attempts were then made to electrolyse anthracine suspended in 20 per cent. sulphuric acid, or in caustic alkali to which an oxygen carrier had been added. Various carriers were employed, the most satisfactory being chromium, cerium or manganese salts.

Geological Society, May 11.—Mr. H. B. Woodward, F.R.S., vice-president, in the chair.—On some quartzite-dykes in mountain-limestone near Snelston (Derbyshire): H. H. **Arnold-Bemrose.** The quartzite of these "dykes" consists of angular detritus, quartz-grains with enclosures, a few small grains of felspar, and a few shreds of mica. The grains are cemented by silica, and sometimes by calcite. The silica is present in the limestone in two forms, which have had an entirely different origin. An important bed of sandstone was found by sinking for a well at Marston Common Farm, and the same bed is found also about 800 feet south of the farm. The microscopic aspect of the rock is precisely similar to that of the dykes. It is at a period later than the Keuper that the silica which cemented the sandstone of the dykes and of the Common Farm appears to have been introduced.—Phenomena bearing upon the age of the Lake of Geneva: Dr. C. S. **Du Riche Preller.** The author has examined the low-level gravel-beds and other alluvia in the Rhone Valley. After describing the phenomena around the Lake of Geneva, and comparing them with those around the Lake of Zurich, he draws the following conclusions:—The low-level gravel-beds of the Rhone Valley near Geneva are fluviatile deposits of the second inter-Glacial period, and were formed before the present deep lake-basin. The high-level gravel-beds of La Côte above Rolle and of the Jorat district above Lausanne are true Deckenschotter. Hence the term "alluvion ancienne" should only apply to the high-level deposits. The formation of the present deep lake-basin of Geneva was primarily due to the lowering of the valley-floor by flexures of the Molasse and its contact-zones, posterior to the maximum glaciation. The author holds that the Lake of Geneva, together with the other principal zonal lakes between the Alps and the Jura, was formed under similar conditions and at the same time as the Lake of Zurich, that is, towards the close of the Glacial period.

Zoological Society, May 17.—Mr. Howard Saunders, vice-president, in the chair.—The fifth of a series of papers by Sir Charles **Eliot,** K.C.M.G., on Nudibranchs from Zanzibar and East Africa, was read. Twenty species were treated of in the paper, of which eleven were described as new.—Mr. G. A. **Boulenger,** F.R.S., described a new species of tree-frog of the genus Hyla, from British Guiana, carrying eggs on the back.—Mr. F. E. **Beddard,** F.R.S., read a paper containing notes on the anatomy of certain species of snakes of the family Boidæ.—A communication from Dr. G. Stewardson **Brady,** F.R.S., contained an account of a collection of Entomostraca made in Natal by Mr. James Gibson. Eleven species were enumerated in the paper, of which nine were described as new, one being made the type of a new genus.

Royal Microscopical Society, May 18.—Dr. Dukinfield H. Scott, F.R.S., president, in the chair.—A note by Mr. A. A. C. Eliot **Merlin** on Mr. Nelson's new formula amplifier was read. The amplifier, which consists of a negative lens placed in the rear of the objective, was calculated by Mr. Nelson at the request of the author to enable him to make some delicate microscopical measurements. With the usual arrangement of a low power eye-piece and screw micrometer, the magnification afforded by objectives of high power was insufficient to ensure accuracy in all cases, and it was not desirable to use more powerful eye-pieces, as the spider lines then appeared too coarse. The author found the amplifier yielded especially good results when used for micrometrical purposes, and he suggested the application of it to students' microscopes for quickly obtaining an increase of magnifying power. Mr. Nelson's formula for the amplifier was given.—A note on Grayson's 120,000 band plate by Mr. **Nelson** was then read. The band was resolved strongly by an apochromatic oil immersion 1/8, 1·43 N.A., and a 5 eye-piece; it was also resolved by a semi-apochromatic 1/10, 1·3 N.A., and a 5 eye-piece, and by an old achromatic water immersion 1/12, 1·2 N.A.; in this case the lines appeared to have irregularities. The 90,000 band was resolved by an apochromatic of 4 mm., 0·97 N.A., quite easily, and by a $\frac{1}{4}$ dry apochromatic $\frac{1}{4}$, 0·96 N.A., with some difficulty. The author remarked in passing that the latest books on physical optics state that 1/90,000 inch is the theoretical limit for microscopic vision. After giving particulars of the resolution of other bands, Mr. Nelson stated that ruled lines are more difficult to resolve than diatoms of equal fineness. He said

the best screen for work of this kind is made from a saturated solution of acetate of copper many times filtered, to which a very small quantity of methylene blue should be added. Sunlight with a heliostat was used, and the light made oblique in one azimuth. The theoretical resolving limit for oblique light may be *roughly* taken at 100,000 times the N.A. of the objective. Dr. Hebb said he saw this plate exhibited at the Royal Society's conversazione, and though it was certainly resolved, he remarked that some of the lines appeared weaker than others. Mr. E. E. Hill said this was due to the fact that the objective used had an aperture of only 1·1 N.A.

DUBLIN.

Royal Dublin Society, April 19.—Prof. E. J. McWeeney in the chair.—Mr. G. H. **Carpenter** read a paper on injurious insects, &c., observed in Ireland during the year 1903. The prevalence of the black-currant mite (*Eriophyes ribis*) in certain districts was mentioned, and attention was directed to the economic importance of some species of springtails (*e.g. Achorutes armatus* and *Lipura ambulans*) on account of their habit of attacking healthy seeds and fruits.—Prof. J. A. **McLelland** read a paper on the penetrating radium radiation. As the γ rays act in some ways more like charged particles than like Röntgen rays, the author has made experiments to test directly whether or not a charge is carried by the γ rays. No charge was detected. The sensitiveness of the apparatus is defined by showing how small a fraction of the β radiation could have been detected by means of the charge on the β particles. The second part of the paper deals with the absorption of γ rays by different substances, and it is shown that these rays are to some extent heterogeneous, and that the absorption-density law is followed with remarkable closeness when one deals only with the most penetrating of the γ rays.—Dr. W. E. **Adeney** made a further communication on photographs of spark-spectra from the 21·5 feet Rowland spectrometer in the Royal University, Dublin. In this paper the author deals with the wave-lengths of the lines in the ultra-violet spark-spectra of platinum and chromium. These have been calculated from measurements made from photographs of the first order of spectra, reproductions of which were published in the first part of this work (*Trans.* Roy. Dubl. Soc., vol. vii., 1901, p. 331). Kayser's measurements of well defined lines in the arc-spectrum of platinum have been employed as standards.—Prof. E. J. **McWeeney** read a paper on the cases of carbon-monoxide asphyxiation that have occurred in Dublin since the addition of carburetted water-gas to the ordinary coal-gas. Attention was first directed to the increase of carbon-monoxide in the Dublin coal-gas by Prof. Emerson Reynolds, F.R.S., in a paper read before the Royal Dublin Society in 1900 (*Scientific Proceed.*, vol. ix. p. 304). Analyses made for Prof. McWeeney by Mr. J. Holm Pollok showed 17·2, 16·8 and 14·6 per cent. of CO respectively. The author proceeded to recount in detail the circumstances attending seven fatal cases that had come under his notice during the past three years, each of which presented special features of interest. In one of the cases, which had a fatal termination, the hæmoglobin of the blood was saturated to the extent of 73 per cent. with carbon monoxide; in another the latter amounted to 87·7 per cent. The victim in this case, a young man, was asphyxiated in his bath by the CO-containing fumes escaping from a badly constructed and unventilated "geyser." The author concluded by emphasising the need for increased caution imposed by the more deadly nature of the gas now supplied.

PARIS.

Academy of Sciences, May 24.—M. Mascart in the chair.—On the limits of sensitiveness for odours and emanations: M. **Berthelot.** The rate of loss of musk and iodoform under certain conditions is compared with emanations from a small quantity of a foreign element mixed with a large quantity of an element not giving an emanation.—On γ-diphenylanthracene and on the hydride of symmetrical γ-diphenylanthracene: A. **Haller** and A. **Guyot.** Phenyloxanthranol reacts with phenyl-magnesium bromide, giving about 50 per cent. of the expected diol. The replacement of the phenyloxanthranol by its methyl ether in this reaction gives a nearly theoretical yield. This, on reduction with sodium amalgam, gives the dihydride of diphenylanthracene.—On some new facts observed by means of a phosphorescent screen: E. **Bichat.** The direct hydrogenation of the homologues of aniline: Paul **Sabatier** and J. B. **Senderens.** By passing a mixture of hydrogen and the vapours of the alkyl-anilines over reduced nickel at 160° C. to 180° C., cyclohexylethylamine, cyclohexyldiethylamine and cyclohexyldimethylaniline have been obtained, the physical properties of which are given. Cyclohexylmethylaniline was obtained with difficulty from methylaniline by this reaction.—The detonation under water of explosive substances: M. **Jacob.** The phenomena of propagation of the motion are completely different in the cases where the coefficient of compressibility is supposed constant and where it is taken as variable. In the first case, the speed of propagation of the motion is constant, in the latter it is variable, and increases with the pressure.—On the energy in the so-called statical actions, its relation with the quantity of motion and its differentiation from the work: Ernest **Solvay.**—The resistance of the air. The comparison of the direct resistances of different aërial vanes; numerical results: Ch. **Renard.** These results were obtained with the dynamometric balance previously described by the author, and prove the law of the square of the velocity to be exact. Numerical results are given for the coefficients of vanes of different shapes.—On an instrument designed to facilitate calculations in screw-cutting: M. **Mœhlenbruck.**—On the thermal ionisation of saline vapours: G. **Moreau.** A current of air drawn through a saline solution is heated in a porcelain tube to about 1000° C., and the conductivity measured. It was found that the ionisation of the potassium salts studied was not analogous to that observed in a flame, where the influence of the acid radical is very small. The mobilities of the ions also differ in the two cases.—The cryoscopic study of solutions of antimony sulphide: MM. **Guinchant** and **Chrétien.** The lowering of the melting point of pure antimony sulphide by varying quantities of lead and silver sulphides was determined by a thermocouple, the temperature being maintained by an electrical resistance furnace of nickel wire. The average cryoscopic constant found was 790. The value for the latent heat of fusion deduced by the application of van 't Hoff's formula was 16·7 calories; the value determined direct was found to be 17·5 calories. The experimental results obtained for the lowering of the melting point of antimony sulphide by metallic antimony are in accord with the view that the antimony is in the atomic condition.—The estimation of atmospheric formaldehyde: H. **Henriet.** The aldehyde is estimated by drawing the air over mercuric oxide mixed with glass wool at a temperature of 250° C., and estimating the carbon dioxide formed. The accuracy of the method was proved by blank experiments with known amounts of formaldehyde. The conclusion is drawn from these experiments that formaldehyde exists in the air in the proportion of from 2 to 6 grams per 100 cubic metres of air, this being very large compared with ozone, which is present to the extent of 2 or 3 milligrams in the same volume. The author proposes to make a study of its physiological action.—A method for the characterisation of the fatty acids: René **Locquin.** The sodium salt of the acid is treated in ethereal solution with monochloracetone, and the acetol ester thus produced transformed into its semicarbazone, the melting point of which is taken. The melting points of five semicarbazones derived from five fatty acids are given.—The transformation of ortho-azo-alcohols into indazyl derivatives: P. **Freundler.**—The limit of combination of diazobenzene and phenol: Léo **Vignon.**—The modifications of the radiations from the nervous centres under the action of anæsthetics: Jean **Becquerel** and André **Broca.** From the variations of the *n*-rays, as measured by the lustre of a phosphorescent screen, the action of the anæsthetic can be followed, the point when danger to life commences and the point of death being easily distinguished.—On a physical proof of the adaptation between natural reagents and their perceptive organs: Augustin **Charpentier.**—The action of the *n*-rays on biological phenomena: M. **Lambert** and Ed. **Meyer.**—On cases of rapid expulsion of calculi by d'Arsonvalisation: A. **Moutier.**—On the sterilisation of cork: F. **Bordas.** Superheated steam was found to give the best results.—Study of the

lypolytic action of the cytoplasma of the castor oil seed: Maurice **Nicloux.**—On the hydrolysing properties of the castor oil seed: Ed. **Urbain** and L. **Saugon.**—On the modifications of the ergographic constants under different experimental conditions: Mlle. I. **Ioteyko.**

DIARY OF SOCIETIES.

THURSDAY, JUNE 2.

ROYAL SOCIETY, at 4.30.—On the Aurora Borealis and the Electric Charge of the Sun: Prof. Svante Arrhenius.—Colours in Metal Glasses and in Metallic Films: J. C. Maxwell Garnett.—On a Direct Method of Measuring the Coefficient of Volume-elasticity of Metals: A. Mallock, F.R.S.—A Method of Measuring Directly High Osmotic Pressures: The Earl of Berkeley and E. G. J. Hartley.—The Advancing Front of the Train of Waves Emitted by a Theoretical Hertzian Oscillator: Prof. A. E. H. Love, F.R.S.—On the General Circulation of the Atmosphere in Middle and Higher Latitudes: Dr. W. N. Shaw, F.R.S—On the Magnetic Changes of Length in Annealed Rods of Cobalt and Nickel: Dr. S. Bidwell, F.R.S.—On the Electric Effect of Rotating a Dielectric in a Magnetic Field: Dr H. A. Wilson.

LINNEAN SOCIETY, at 8.—The Species of Impatiens in the Wallichian Herbarium: Sir Jos. D. Hooker, G.C.S.I., F.R.S.—Biscayan Plankton. Part III. Chætognathia: Dr. G. H. Fowler.—The Flow of Fluids in Plant-stems: Prof. R. J. Anderson.

RÖNTGEN SOCIETY, at 8.30.—Experiments to Determine the Effects of Form and Winding upon Resonance Phenomena: Dr. Clarence A. Wright.

INSTITUTION OF MINING ENGINEERS, at 11 a.m.—Suggestions respecting the Institution of Mining Engineers: Prof. R. A. S. Redmayne.—Coal-mining in the Faroe Islands: G. A. Greener.—Tin-mining in the Straits Settlements, with a few Notes regarding Chinese Labour: W. T. Saunders.—Underground Temperatures, especially with regard to Coal-mines: Dr. Hoefer.—The Hammer-Fennel Tachymeter-theodolite: A. O. Eoll.—Notes on the Report of the Departmental Committee on the Use of Electricity in Mines: Sydney F. Walker.—A Comparison of Three-phase and Continuous Currents for Mining Purposes: Roslyn Holiday.—Electric and Compressed-air Locomotives: B. S. Randolph.—Work of Conveyors on Longwall Faces: Robert G. Ware.

CHEMICAL SOCIETY, at 8.—*iso*Nitrosocamphor: M. O. Forster.—Imino-Ethers and Allied Compounds corresponding with the Substituted Oxamic Esters: G. D. Lander.—The Action of Heat on α-Hydroxycarboxylic Acids: Part I. α-Hydroxystearic Acid: H. R. Le Sueur.—The Basic Properties of Oxygen. Additive Derivatives of the Halogen Acids and Organic Compounds and the Higher Valencies of Oxygen. Asymmetric Oxygen: E. H. Archibald and D. McIntosh.

FRIDAY, JUNE 3.

ROYAL INSTITUTION, at 9.—The Development of the Theory of Electrolytic Dissociation: Prof. Svante Arrhenius.

INSTITUTION OF MINING ENGINEERS, at 10.30 a.m.—The Firing of Babcock Boilers with Coke-oven Gases: T. Y. Greener.—Explosives and Lamp Testing Station at Frameries: Victor Watteyne.—The Transvaal Kromdraai Conglomerates: A. R. Sawyer.—The Southern Rand Goldfield: A. R. Sawyer.—The Occurrence of Cinnabar in British Columbia: G. F. Monckton.—Prevention of Accidents in Winding: John H. Merivale.—Petroleum and its Use for Illumination, Lubricating and Fuel Purposes: P. Dvorkovitz.—The Analytical Valuation of Gas Coals: G. P. Lishman.—A New Process of Chlorination for Mixed Gold and Silver Ores: H. F. Brown.—Graphite-mining in Ceylon and India—Part I. Ceylon: G. A. Stonier.

GEOLOGISTS' ASSOCIATION, at 8.—The Geology and Prehistoric Anthropology of the Hastings District, with Special Reference to the Excursion of June 11: W. J. Lewis Abbott.

SATURDAY, JUNE 4.

ROYAL INSTITUTION, at 3.—Spitsbergen in the Seventeenth Century: Sir W. Martin Conway.

MONDAY, JUNE 6.

SOCIETY OF CHEMICAL INDUSTRY, at 8.—The loss of Nitre in the Chamber Process: J. K. H. Inglis.—Acetone—its Manufacture and Purification: A. Marshall.—A New Method for the Estimation of Tannin: J. Gordon Parker and E. E. M. Payne.

ARISTOTELIAN SOCIETY, at 8.—Primary and Secondary Qualities: Prof. G. F. Stout.

INSTITUTE OF ACTUARIES, at 5.—Annual General Meeting.

TUESDAY, JUNE 7.

MINERALOGICAL SOCIETY, at 8.—On Cobaltiferous Mispickel from Norway: Rev. Mark Fletcher.—On an Improved Form of Refractometer: G. F. Herbert Smith.—Notes on the Development of the Kimberley Diamond Mines, with Lantern Illustrations: Prof. H. A. Miers, F.R.S.

ZOOLOGICAL SOCIETY, at 8.30.—On some New or little-known Butterflies, mainly from High Elevations in the N.E. Himalayas: Lieut.-Col. J. Malcolm Fawcett.—On Seasonal Phases in Butterflies: Dr. A. G. Butler.—Note on an Apparently Abnormal Position of the "Brephos" within the Body of a Skink (*Chalcides lineatus*): F. E. Beddard, F.R.S.—On the Rare Rodent *Dinomys branickii*, Peters: Dr. E. A. Goeldi.—On the Black Wild Cat of Transcaucasia: C. Satunin.—On a Buffalo Skull from East Central Africa: R. Lydekker.—On Two New Labyrinthodont Skulls: Dr. A. Smith Woodward, F.R.S.

WEDNESDAY, JUNE 8.

GEOLOGICAL SOCIETY, at 8.—The Palæontological Sequence in the Carboniferous Limestone of the Bristol Area: A. Vaughan.—The Evidence for a Non-Sequence between the Keuper and Rhætic Series in North-west Gloucestershire and Worcestershire: L. Richardson.—On a Small Plesiosaurus-Skeleton from the White Lias of Westbury-on-Severn: W. F. Gwinnell.

VICTORIA INSTITUTE, at 4.30.—Annual Meeting. The President, the Lord Chancellor, F.R.S., will deliver the annual address.

THURSDAY, JUNE 9.

ROYAL SOCIETY, at 4.30.—*Probable Papers*:—On the Ossiferous Cave-Deposits of Cyprus, with Descriptions of the Remains of *Elephas cypriotes*: Miss D. M. A. Bate.—On the Structure and Affinities of Palæodiscus and Agelacrinus: W. K. Spencer.—On the Physical Relation of Chloroform to Blood: Dr. A. D. Waller, F.R.S.—Contributions to the Study of the Action of Sea-Snake Venoms: Sir Thomas R. Fraser, F.R.S., and Major R. H. Elliot, I.M.S.—On the Action of the Venom of *Bungarus coeruleus* (the Common Krait): Major R. H. Elliot, I.M.S., W. C. Sillar and G. S. Carmichael.—On the Combining Properties of Serum-Complements and on Complementoids: Prof. R. Muir and C. H. Browning.—Notes on the Statolith Theory of Geotropism: F. Darwin, For.Sec.R.S., and D. F. M. Pertz.

MATHEMATICAL SOCIETY, at 5.30.—The Application of Poisson's Formula to Discontinuous Disturbances: Lord Rayleigh.—Some Expansions for the Periods of the Jacobian Elliptic Functions: H. Bateman.—Types of Covariants of any Degree in the Coefficients of Each of Any Number of Binary Quantics: P. W. Wood.

INSTITUTION OF ELECTRICAL ENGINEERS, at 5.—Annual General Meeting.

FRIDAY, JUNE 10.

ROYAL ASTRONOMICAL SOCIETY, at 5.

PHYSICAL SOCIETY, at 8.

MALACOLOGICAL SOCIETY, at 8.—On *Damayantia smithi*, Godwin-Austen and Collinge: Lt.-Col. H. H. Godwin-Austen.—Descriptions of Twenty-nine Species of Gastropoda from the Persian Gulf, Gulf of Oman, and Arabian Sea, dredged by Mr. F. W. Townsend, 1903-4: J. Cosmo Melvill.—*Conus Coromandelicus*, Sm, its Probable Affinities and Systematic place in the family Conidæ: J. Cosmo Melvill.—Descriptions of New Marine Shells from the Collection of the late Admiral Keppel: G. B. Sowerby.—Note on *Voluta brazieri*, Cox: E. A. Smith, I.S.O.—On *Doris planata* of Alder and Hancock: Sir C. Eliot, K.C.M.G.—Description of a Helicoid Land Shell from Central Australia: J. H. Ponsonby.—On Some Semi-fossil Land Shells found in the Hamakua District, Hawaii: C. F. Ancey.

CONTENTS.

THURSDAY, JUNE 9, 1904.

AN AMERICAN TREATISE ON NAVAL ARCHITECTURE.

Naval Architecture. By Prof. C. H. Peabody. Pp. v+616. (New York: Wiley and Sons; London: Chapman and Hall, Ltd., 1904.) Price 31*s.* 6*d.* net.

SINCE the revival of shipbuilding in the United States and the construction of the "New Navy," courses of instruction in naval architecture have been arranged at several of the universities and technical institutes. The Massachusetts Institute of Technology has taken a leading position in this matter, and has provided classes for those intending to enter the profession of shipbuilding, as well as a post-graduate course in naval architecture especially arranged for assistant constructors whose preliminary training is at the Naval College, Annapolis. For many years the Navy Department of the United States had to send their assistant constructors to Europe for instruction. The first students who so came were entered at the Royal Naval College at Greenwich; in later years many young American naval architects have been students at Glasgow University. Others have been sent to the French School of Naval Architecture. For the future, it would appear that the United States intend to supply their own educational wants in this as in other branches.

The author of the book under review is the professor of naval architecture and marine engineering in the Massachusetts Institute of Technology, and it is obvious that the book has grown largely out of his professorial work. It is also apparent that Prof. Peabody has considerable sympathy with French methods. Indeed, he adopts several French technical terms instead of their usual English equivalents, and in certain sections of the book he gives prominence to French methods as distinguished from English. While this comprehensive treatment is praiseworthy, no sufficient reason is seen for departure from the accepted terminology of English treatises on the subject.

The book is intended "to give, in a consistent and connected form, the commonly accepted theory of Naval Architecture," and it is added, "while this work is intended primarily for students, it is hoped that it may be found useful by Naval Architects and Shipbuilders in general." It is probable that this hope will be realised, so far as those sections of the book are concerned which deal with ordinary ship calculations for displacement and stability, or those illustrating many practical operations connected with the addition, removal, or transfer of weights carried by ships. Herein Prof. Peabody bases his treatment upon the frank adoption, in practice, of mechanical aids to calculation which have been introduced during the last twenty-five years, chiefly by Amsler. Naval architects owe much to that great instrument maker, and can effect with his integrators an enormous economy of labour and a great increase of speed in obtaining important results. The planimeter for many years stood alone, but when Amsler learned that, in addition to the determination of areas, it was important in the designing of ships to obtain also *moments,* and *moments of inertia,* of areas about assigned axes, he speedily produced ingenious machines which could be used by ordinary draughtsmen. These instruments were first adopted in this country, and are now generally employed.

Prof. Peabody gives a clear account of the principles and methods of use of integrators. Moreover, he furnishes an excellent summary of the latest modes of arranging the actual details of work for ships' calculations. In this department very considerable advances have been made during the last thirty years since calculations for the stability of ships became general. But while, from the draughtsman's point of view, the book is, for the most part, admirable, it does not treat with equal fulness some calculations of considerable importance, particularly those relating to weight and strength. For these his treatment can hardly be described as "up to date," or as giving full and complete information to students or calculators. There is, in fact, a want of due proportion in the space and attention devoted to the various sections. Prof. Peabody, while aiming at giving a consistent and connected account of the whole accepted theory of naval architecture, devotes particular attention to certain portions of the subject, and unduly compresses his treatment of others. Some of his longest chapters, while they are undoubtedly interesting and valuable as compilations of existing treatises on special branches of the science of shipbuilding, have not, as a matter of fact, great practical value. The theory of waves, for example, including an outline of the stream-line theory of resistance, occupies nearly one-eighth of the book, and is treated in some portions with a mathematical detail that appears inappropriate in this work, where the principal conclusions might have been given and reference made to the original authorities for the mathematical proofs.

Again, in dealing with the propulsion of ships, much space is devoted to the practical reproduction of parts of well known books dealing with the design and efficiency of screw-propellers, such as that published in England by Mr. Sidney Barnaby, and that first issued in the United States by Naval Constructor Taylor, who was a graduate of our Royal Naval College. Both these gentlemen based their work chiefly on experiments made, or on methods suggested, by the late Mr. William Froude and Mr. R. E. Froude, and furnished valuable rules for guidance in practice; but as their books are accessible, they need not have been so largely drawn upon. Having done this, Prof. Peabody was practically compelled to abridge very greatly his treatment of other sections of great importance in the current work of ship designing, wherein students might have been greatly assisted if more extended descriptions and investigations had been given.

Another feature in which the volume is not entirely satisfactory is in some of its illustrations of actual practice, and in its allusion to broad general rules

followed by naval architects in endeavouring to secure good qualities in ships. For instance, Prof. Peabody, when dealing with the question of "metacentric heights," which are the measures of the "stiffness" of ships, their power to resist inclination under the action of external forces, states that, in practice, this height "is seldom less than $1\frac{1}{2}$ feet and seldom more than 5 feet unless it be in special forms," and then remarks that "it appears that the metacentric height for steamships is somewhere near the same for all steamships whatever their size," which is obviously incorrect on his own showing, and might easily lead students to conclude that little importance attaches to the value of the metacentric height within a very wide range; whereas it is absolutely certain, and is elsewhere recognised by Prof. Peabody, that the more moderate the metacentric height the greater is the probability of steadiness in a seaway. He also states that "metacentric height may be controlled by varying the proportion of beam to length," and does not specifically direct attention to the much greater influence of variation in the proportion of beam to draught.

In another passage he refers to the characteristic features in the curves of stability of sailing ships and steamships, and makes the generalisation that this is chiefly due to the greater metacentric height and greater freeboard of sailing ships; whereas it is perfectly well known that other considerations have larger practical effect on the curve of stability. Many sailing ships having great range of stability have only very moderate metacentric heights and moderate freeboard. Few allusions are made to the details of practical shipbuilding, and some of these indicate that the author can have had but little experience in the conduct of actual work.

These criticisms are not intended to indicate any general disapproval of the scope or character of the book. It is no doubt intended to be used as an auxiliary to class-teaching by competent professors, and for this purpose it will be extremely useful. It also compiles and brings together much information appearing in the *Transactions* of the English Institution of Naval Architects or of similar societies in other countries, and practically reproduces the essential parts of standard treatises by other authors on particular branches of the subject. Prof. Peabody makes no claim to originality, and states frankly that free use has been made of numerous works on naval architecture, as well as of original articles and memoirs. His readers have to thank him for the labour he has bestowed upon this task, and, as a compilation, the book will be useful for reference to naval architects generally. But it does not profess to be—nor, indeed, within its compass could it possibly be made—a complete treatise on the modern theory of naval architecture. Such a treatise has yet to be written, and the advances made in recent years in both the theory and practice of ship construction have been so considerable that the work of preparing it would be very heavy. It is wanted, however, and no doubt will eventually be produced.

W. H. White.

NEW ELECTRICAL TEXT-BOOKS.

A Text-book of Static Electricity. By H. Mason. Pp. vi+155. (New York: McGraw Publishing Co., 1904.) Price 2 dollars.

Dynamo, Motor, and Switchboard Circuits. By W. R. Bowker. Pp. xi+120. (London: Crosby Lockwood and Son, 1904.) Price 6*s*. net.

Testing of Electromagnetic Machinery and Other Apparatus. By B. V. Swenson and B. Frankenfield. Pp. xxiii+420. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1904.) Price 12*s*. 6*d*. net.

The Alternating Current Transformer. By F. G. Baum. Pp. vii+195. (New York: McGraw Publishing Co., 1903.) Price 1.50 dollars.

The Induction Motor. By H. B. de la Tour. Translated by C. O. Mailloux. Pp. xxvii+200. (New York: McGraw Publishing Co., 1903.) Price 2.50 dollars.

The subject of electrostatics is not *per se* one of very great importance either to the electrical engineer or the student of electricity, and it is open to question whether a text-book devoted to the elementary principles of the subject is much needed. Still, there is something to be said for having collected together between one pair of covers all the information which is usually only to be found scattered somewhat irregularly throughout the pages of a more comprehensive manual. Mr. Mason opens with a discussion of the general principles of electrostatics, and proceeds to consider in more detail capacity, electrostatic instruments, and static generators. The fact that there is not very much to say and plenty of space in which to say it has enabled the author to make his descriptions very complete and clear, and the further advantages of large type and numerous illustrations should help to make the book a very useful work of reference.

Mr. Bowker's book consists chiefly of diagrams of connections, with short explanatory notes: the number of different cases considered is very large—there are over a hundred diagrams—and these cover practically all the more important circuits with which an electrician is likely to have to deal, whether in direct current, single phase, or polyphase work. We do not doubt that the book will prove useful to those who are concerned rather with connecting up machinery than with electrical engineering, but we should hardly have thought that the matter was of sufficient importance to warrant its treatment as a separate study.

The work on the testing of electromagnetic machinery by Messrs. Swenson and Frankenfield is the first of two volumes, and deals only with direct-current machinery. It is a book which can be thoroughly recommended to all students of electrical engineering who are interested in the design, manufacture, or use of dynamos and motors. After a brief introduction, which contains, incidentally, some excellent advice on the writing of reports (which advice, by the way, the authors themselves transgress in the specimen report which they print), the authors give a series of nearly a hundred tests, which are well chosen and

clearly explained. A distinct and valuable feature of the book is the list of references at the beginning of each test to the principal text-books and papers dealing with the subject of the test. The book is well illustrated, and there is a useful chapter at the end on commercial shop tests.

The two books by Mr. Baum and M. de la Tour cover, in a satisfactory manner, two very important branches of alternating-current work on which not very much has yet been written in the way of text-books. This is especially the case with M. de la Tour's treatise on the induction motor, which is very comprehensive and certainly the best book as yet written on this subject. Mr. Baum's book is not so full, but it contains an excellent discussion of the theory and construction of transformers, which should prove very useful to students. It is difficult to understand why chapter ii. has been included at all, since the method given in it is not only unsatisfactory but, even in the author's own opinion, "always produces confusion in the mind of the student." There is a good final chapter on commercial transformers. M. de la Tour also leavens his theory with a little practical application of it, the last chapter but one being devoted to the design in very careful detail of three different induction motors. A word of praise is also deserved by the translator for the excellent way in which he has performed his task of presenting M. de la Tour's book to the English public.

M. S.

FROM BUFFON TO DARWIN.

Controverses Transformistes. By Alfred Giard. Pp. viii + 178. (Paris: C. Naud, 1904.) Price 7 francs.

THIS is an interesting book, written, like nearly all French scientific books, in transparently clear style. It assumes, however, that the reader has a fair knowledge of zoology, so that it hardly appeals to the reading world in general. It is intended rather for those who have made some study of comparative anatomy, and who wish for light on the various theories of evolution. In France Darwinism has not had the triumphant progress that it has had in England and, still more, in Germany. Even evolution, quite apart from the specially Darwinian interpretation of it, has been very slowly accepted, so that the earlier part of M. Giard's book deals with controversies that for us have long been buried. The second chapter, which originally appeared as an article in the *Revue scientifique* in 1874, discusses at length the question whether the ascidians are really near allies of the vertebrates. A figure of the larva of a typical ascidian is given, but it would have been well to give also a figure of Appendicularia, in which the notochord persists in the adult. Throughout, the book would have gained by being more amply illustrated. The chapter on ascidians combats von Baer's now exploded theory of them, perhaps at rather unnecessary length. But the author has deliberately adopted the plan of reprinting his essays written during the last quarter of the nineteenth century so that the reader may appreciate the difficulties against which the evolutionist has had to contend.

Chapter iii. deals with systems of classification that have had their day, systems which accepted each type of organism as an existing fact without attempting to account for it. M. Giard is heart and soul an embryologist. Kowalevsky is to him a far greater man than the greatest master of anatomy pure and simple who has had no grand hypothesis to guide him.

In chapter iv., on the factors of evolution, we enter on more controversial ground. M. Giard is a Lamarckian. He has a great reverence for Darwin, but Lamarck is put on a loftier pedestal. Lamarck, he holds, made known the great primary factor of evolution. Darwin introduced an important factor, but still a secondary one. In some cases M. Giard owns that the Lamarckian principle will not account for everything, *e.g.* for all the characters of a newborn mammal. Darwinism must then be called in. In chapter v. (1898) Weismann appears as a conspicuous figure on the stage. M. Giard will not allow Weismann to send Lamarckism to the limbo of worn out theories. He refers to the experiments of Brown-Séquard on guinea-pigs as proof that Lamarck was right. He accepts telegony as a fact telling strongly in Lamarck's favour, though men of science are coming to regard it as a breeder's superstition. Throughout his discussion of the question of acquired characteristics there is a certain confusion of thought. He draws a marked distinction between the characters that result from external conditions and those which spring from forces at work within the animal. Yet external influences can only stimulate the organism to show the stuff that it is made of. It responds to a stimulus. New characters become apparent, but are not, strictly speaking, acquired.

F. W. H.

OUR BOOK SHELF.

A Text-book of Quantitative Chemical Analysis. By Frank Julian. Pp. 604. (St. Paul, Minn.: The Ramsey Publishing Co., 1902.) Price 25*s.* net.

THE book is so excellent as far as it goes, except in the quality of the paper and the print, that it seems a pity it goes no farther. A little more elaboration would have converted it into a really serviceable manual. The reviewer has failed to discover any important omission among the special methods with which he happens to be familiar, but there is an absence of detail, which, it cannot be too often insisted on, deprives any treatise on analysis of much of its practical value. The chemist whose business it is to analyse cannot afford the time to elaborate methods for himself. The fact, of course, is not overlooked that the book is written for students, and no doubt the student is expected to supply any gaps which may occur. But apart from a chapter of typical exercises in analysis, it is difficult to see in what sense the book can be called a student's text-book, unless, indeed, the student is qualifying for the post of analyst.

And this raises the interesting question, into which there is no occasion to enter here, of how far analysis should be carried as a part of a general chemical training as distinguished from a specialised study. There can be little doubt that the kind of skill and knowledge which a public or works analyst requires must be met by a special training in a laboratory set apart for the purpose.

What a student of general chemistry needs, after

his preliminary qualitative study of the elements, is a knowledge of a few typical processes carefully selected to illustrate the principles of quantitative analysis.

It is for this reason that the exercises which form part ii. of this volume have much to recommend them. Those who are accustomed to the old system, which probably originated in Berzelius's laboratory, of analysing a few inorganic salts and then a series of minerals, will probably be startled at finding such an incongruous collection as lead carbonate, sodium chloride, coffee, cast iron, vinegar, &c., following one another. Yet when one considers how few students, after taking a substantial course in practical chemistry, could suggest a means for distinguishing between lard and vaseline, or benzene and petroleum, except by their smell, it must be admitted that a practical acquaintance with common materials in the form of analysis has many advantages.

Perhaps the best way of estimating the value of a book is to ask oneself whether one would care to possess it For those who are interested in any kind of general or technical analysis, this question may be safely answered in the affirmative. J. B. C.

Catalogue of the Mesozoic Plants in the Department of Geology, British Museum (Natural History). The Jurassic Flora. II. Liassic and Oolitic Floras of England (excluding the Inferior Oolite Plants of the Yorkshire Coast). By A. C. Seward, F.R.S. Pp. xv + 192. Plates i–xiii. (London: Printed by Order of the Trustees of the British Museum, 1904.)

The concluding part of Mr. Seward's catalogue of the Jurassic floras makes the catalogue a nearly complete treatise on the known fossil remains of plants from the Trias, Rhætic, Lias and Oolite of England. In the present volume are included plants from Jurassic rocks in various parts of England, together with a few from the Coralline Oolite and Liassic strata of East Yorkshire. A short account is also given of such Triassic and Rhætic plants as are represented in the British Museum.

Die Kathodenstrahlen. By G. C. Schmidt. Pp. vi + 120. (Brunswick: Vieweg und Sohn, 1904.) Price 3 marks.

This book contains a concise and complete account of the properties of kathode rays, presented in an elementary way, together with as much information on the electric discharge and allied phenomena as is necessary for their comprehension.

The information is brought well up to date and references to the original papers are given. The book should prove of use to those wishing for a connected account of the subject in a readable form devoid of mathematical analysis. The fifth chapter contains a short but interesting account of the historical development of the theory of the electric discharge and kathode rays. H. A. W.

An Introduction to Metal Working. By C. J. Pearson. Pp. 106. (London: Murray, 1904.) Price 2s.

This little book is evidently intended to describe the ordinary tools used in the working of metals, although the author does not tell us so. These descriptions are of an elementary nature, and well suited for young students in the early stage. The book is fully illustrated with woodcuts, as well as with some very excellent photographs of operations, the latter being a distinct novelty in a technical book. The author uses simple language, he knows what he is writing about, and we feel sure that his little work will be much appreciated by junior students, apprentices and others, to whom we strongly recommend it.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of Nature. *No notice is taken of anonymous communications.]*

A Dynamical System illustrating the Spectrum Lines.

In Nature of March 10, which I received yesterday, Prof. Schott remarks that the dynamical system illustrating the spectrum lines, which I communicated to Nature of February 25, is unstable. This evidently rests on a misunderstanding, because the system which I have discussed is not identical with that which was investigated by Prof. Schott. I believe that the statement, "such an ideal atom will not be contradictory to the results of recent experiments," led Prof. Schott to suppose that the system which I considered must be electrically neutral. Those who have read Maxwell's paper on the stability of Saturn's rings will admit, without Prof. Schott's comment, the futility of discussing an *electrically neutral* system with a central positive charge and a ring of negative electrons as satellites.

The system which I have investigated is not electrically neutral, but the central charge is supposed to be very large compared with the negative charges in the ring. Since q (using Prof. Schott's notation) is great compared with J or K, the ring is generally stable; the proof for stability can be given in a more general manner.

To prevent further misunderstanding, it will be necessary to explain how I was led to investigate such a system instead of an electrically neutral one. As the principal aim of the investigation was to discuss the small oscillations which will illustrate the regularity in line and band spectra, it was necessary to have a hypothetical atom, which will have some resemblance to an actual one, and the motion of which can be treated by means of simple mathematical analysis. Recent investigations show that a chemical atom is associated with numerous electrons, which in the lightest element amount to several hundred, while in heavy atoms the number may reach a hundred thousand. We have reason to believe that these electrons are not crowded together in spite of their large number. In making abstraction as to the hypothetical atom, we may conveniently assume the central positive charge to form a neutral system with all the negative electrons, but only a small fraction of the latter to be found in the ring the oscillation of which is the subject of investigation. The rest of the negative electrons may either describe their isolated orbits, or may form some other regular systems. These will evidently cause disturbances in the ring, which I have not calculated, inasmuch as it was necessary to introduce further assumptions as to the orbits or the arrangement of electrons. As a dynamical system illustrating the regularity in spectrum lines, I have assumed the ring and the central positive charge as an ideal atom, leaving the remaining electrons outside the domain of investigation.

Further evidence as to the validity of such an hypothesis is afforded by the fact that spectrum lines of most elements are not all subject to a regular law, but that there are a great many characteristic lines the position of which is not expressible by a simple mathematical formula. Moreover, the complexity in the structure of spectrum lines will probably find simple explanation by the perturbations due to stray electrons. These considerations point to the view that only a small part of the negative electrons accompanying an atom should be arranged in a ring, in order to approximate to the real state of a chemical atom.

There is no doubt that Prof. Schott will have good opportunity of applying the mathematical investigations of C. Neumann and Hicks in discussing the oscillations of three rings, just as Lindemann made use of Lamé's functions in studying the spectrum lines as due to the vibration of ellipsoidal atoms, but I am afraid that the result will be difficult of interpretation.

I take this opportunity of introducing a small omission in my former letter to Nature for February 25 (p. 392, second column, line 31 from bottom); after "in opposite senses" add "in a magnetic field."

I may further add that the formula for band spectrum,

$$n' = \omega' + a'm'^2 + b'm'^3 + c'm'^4 + d'm'^5 + \ldots$$

which I have deduced as an extension of Deslandre's formula, is one of the empirical formulæ used by Kayser and Runge for cyanogen bands (*Abhandl. d. Berlin. Akad. d. Wissensch.*, 1889, formula I_a). From $m' = 0$ to $m' = 150$, the difference in wave-lengths between calculation and observation seldom exceeds $\pm 0 \cdot 03 \times 10^{-10}$ m., which is quite within errors of observation. H. NAGAOKA.

Physical Laboratory, Tokyo University, April 20.

Electromotive Force between Two Phases of the same Metal.

I WAS much interested in the letter of Mr. George Beilby in your issue of May 12. It may interest Mr. Beilby to know that I contributed a paper to the Institution of Civil Engineers on "The Effect of Stress on the Corrosion of Metals" (*Proc.* Inst. C.E., vol. cxviii., session 1893–4). On perusing this paper it will be seen that the results were somewhat analogous to the line of investigation Mr. Beilby is undertaking. The experiments were on an extensive scale, and were made on numerous samples of iron and steel. In each case a polished bar of the steel or other metal, of known chemical composition and physical properties, used was cut in two; one half was stressed, and the other remained in its normal state. Each pair of bars was immersed in sea water, as an electrolyte, forming the elements of a galvanic couple, with a delicate calibrated galvanometer in circuit, when a decidedly measurable E.M.F. was observed. It was invariably noticed that the alteration in the physical properties of the metals produced by the stress only in each stressed bar was sufficient to place that bar in the position of copper in a zinc copper cell, the normal unstressed bar answering to the zinc element in a galvanic couple.

A current is also set up between two polished bars of the same metal immersed in a suitable electrolyte, one being in its normal state and the other having had its microcrystalline structure altered by annealing, in the manner illustrated in a recent paper to the Institution of Civil Engineers ("Effects of Annealing on Steel Rails," by Thomas Andrews and Charles Reginald Andrews, *Proc.* Inst. C.E., vol. clvi., session 1903–4, part ii.). When a metal is stressed a similar effect is produced. I have for some time past been working on a research on the E.M.F. between normal and annealed metals, using in one part of the investigation a complete series of specially prepared pure iron and steel bars of varied and known chemical composition, the object of the investigation being to show the E.M.F. produced between annealed and unannealed metals. I am much pleased to learn that Mr. Beilby is also working on this very interesting subject.

Mr. Beilby may also be interested in a research which I made some years ago showing the E.M.F. produced between polished bars of platinum or other metals, cut from the same bar, the E.M.F. being attributable to difference of molecular structure induced by heating one of the bars. The electrolytes employed for these experiments were fused salts at a high temperature (see "Electrochemical Reactions between Metals in Fused Salts," by Thomas Andrews, *Trans.* Royal Society, Edinburgh, session 1885–6). I venture to suggest that the following papers ("Observations on Variations of the Electromotive Force between Metals at High Temperatures in Fused Salts," *Trans.* Royal Society, London, 1885; "Electrochemical Effects on Magnetising Iron," parts i., ii., iii., iv., *Trans.* Royal Society, London, 1887, 1888, 1889, 1892), which I published some time ago, may perhaps be helpful to Mr. Beilby in the course of his researches, the results of which I am looking forward to with much interest and pleasure. THOS. ANDREWS.

Wortley, near Sheffield, June 3.

Graphic Methods in an Educational Course in Mechanics.

IN company, I think, with other correspondents, I have misunderstood Mr. Larden's use of the words "analytical methods." He alluded, it is true, to resolution and taking moments, but "analytical methods," especially when used in contradistinction to "graphical," have a much wider and more commonly received meaning. Dr. Murray's dictionary defines modern mathematical analysis as "the resolving of problems by reducing them to equations," and cites Hutton, "Course Math.," 1827, "Analysis or Analytical method is that which is commonly used in Algebra." Prof. Croom Robertson, in "Analysis" in the "Ency. Brit.," says:—"In modern times analysis has come to mean the employment of the algebraical and higher calculus, and synthesis any direct treatment of the properties of geometrical figures, in the manner of the ancients without the use of algebraical notation or transformations." "Analytical" is a hard-worked word, like potential and polarisation, and no doubt it may be used in Mr. Larden's sense. The word "analytical," in the sense of the employment of algebra and the higher calculus, is not self-explanatory, and "graphical" or "geometrical" are better for this reason than "synthetical," unless the philosophical aspect is under discussion.

There can be no question that for almost all mathematical calculation and research, algebraical methods are far more powerful than geometrical (but I make reservations), and teachers are perhaps for this reason apt to think that they are more useful and better suited for educational explanations of phenomena or of natural laws. If in mistaking Mr. Larden for an unusually pronounced teacher of this type I have protested too strongly, I apologise, but his parenthetical queries which I have provoked I deny.

That some persons have accurate musical "ears," and others "no ear for music," that some can draw excellently without having been taught, and others can never learn, may perhaps be explained by physiological psychology. Some are "good at languages," and others bad; some have a "good head for figures," and others not. Experts in pedagogy might be able to tell us whether this is due to some selective ability or inability. But that some persons use algebra and the calculus with facility, and are bored by geometry, while others have "no head for algebra," but have an aptitude for geometrical methods, seems to be a matter worthy of investigation by the mental philosopher.

Not only has Mr. Larden used "analytical" in a somewhat restricted sense, but in this discussion he limits "graphic methods" to "those methods that depend on accurate drawing only, there being no calculation. . . ." I will give one example of what I mean by a graphical method in an educational course. The fundamental idea of a differential coefficient is explained in the old text-books purely by symbols. Persons with "no head for algebra" find the greatest difficulty in grasping the idea. But draw a curve of speeds on the black-board, and explain that a tangent to it, or the slope at any point, gives the acceleration or rate of increase. You need no accurate drawing, no calculation, no algebra, but you give a perfectly clear idea of a differential coefficient.

It is rather hard that those who are called calculus dodgers cannot discuss the relative advantages of algebraical and geometrical methods without being accused of writing against mathematics or deprecatingly of mathematicians.

Westminster, June 6. A. P. TROTTER.

Association of Economic Biologists.

FOR some time past workers engaged upon various problems connected with economic biology have felt the need of some organisation whereby they could meet from time to time to discuss these different problems with fellow-workers so as to bring out suggestions and to prevent unnecessary duplication of work, and generally to promote and advance the economic side of biological science.

With a view to the formation of such an association of economic biologists, I have briefly discussed the matter with a few fellow-workers, and I shall be pleased to receive an expression of opinion or suggestions from any others.

The idea at present in my mind is an association somewhat on the lines of the American one, which would include and welcome all investigators and teachers in economic biology in its widest sense.

Mr. Fred. V. Theobald (Wye) writes:—"Your suggestion for an Association of Economic Biologists is most excellent.

. . . I will certainly do all I can to promote any such idea."

Mr. Robert Newstead (Chester) writes:—"You would have my heartiest support in the matter, as I feel that such an institution would be of material benefit to the Agriculturists and Horticulturists of this country."

Mr. A. E. Shipley (Cambridge) writes:—"I should welcome the founding of an Association of Economic Biologists if you think we are really strong enough. . . . If the Association is formed I hope it will be a really working one."

Mr. Cecil Warburton (Cambridge) writes:—"I heartily approve of your suggestion with regard to the formation of an Association of Economic Biologists in this country."

Similar letters or expressions of opinion have been received from Dr. A. H. R. Buller, Mr. Herbert Stone, and others.

Walter E. Collinge.

The University, Birmingham, May 30.

THE RELATION OF HUMAN TO BOVINE TUBERCULOSIS.

The Royal Commission appointed to inquire into the relation of human and animal tuberculosis has presented an interim report published on June 1. The Commission was appointed in August, 1901, soon after Prof. Koch's address had been delivered at the British Congress on Tuberculosis held in London in July, 1901, in which he stated that as the result of experiments on animals, cattle, pigs, asses, sheep, and goats, he "felt justified in maintaining that human tuberculosis differs from bovine tuberculosis, and cannot be transmitted to cattle," and he also stated that "though the important question whether man is susceptible to bovine tuberculosis at all is not yet absolutely decided, and will not admit of absolute decision to-day or to-morrow, one is, nevertheless, at liberty to say that, if such a susceptibility really exists, the infection of human beings is but of very rare occurrence. I should estimate the extent of the infection by the milk and flesh of tuberculous cattle and the butter made of their milk as hardly greater than that of hereditary transmission, and I, therefore, do not deem it advisable to take any measures against it." According to Koch the chief danger of infection is from human tuberculous sputum. He suggested as the most important means of combating the disease the improvement of general hygienic conditions, provision of suitable hospitals and sanatoria for consumptives, and inspection and disinfection.

Lord Lister, at the conclusion of Prof. Koch's address, struck a note of warning. He pointed out "how serious and grievous a thing it would be if the rules now in force for securing purity of milk supply should be relaxed, and it should turn out after all that the conclusion was erroneous." This attitude was taken up by a number of other leading pathologists. Since Koch's statement a number of workers have published the results of experiments on the subject, and the bulk of the evidence has been opposed to Koch's view.

The most striking and interesting pronouncement on the subject has been from one of Koch's most distinguished pupils, von Behring, who on this subject places himself in a position entirely opposed to that of his old master. To many minds von Behring's view appears to be as extreme as Koch's. He holds that "the main source to which phthisis must be traced is the milk diet of infants." He found that in young animals such as guinea pigs, owing to the incomplete continuity of the epithelium, numerous bacilli, and among them the tubercle bacillus, could pass through the wall of the alimentary canal, giving rise to a tuberculosis of the cervical glands of the type of scrofula in the human subject, and that at a later period these animals not infrequently developed a type of tuberculosis which has been regarded as indicative of inhalation tuberculosis. The freedom with which milk-bacilli find their way through the walls of the alimentary tract into the circulation owing to the incomplete continuity of the epithelium and absence of active ferment secretion in young animals makes "the disposition to tuberculous infection entirely physiological and normal." At a later period in life a similar susceptible state may be induced by the exanthemata such as scarlet fever and measles. Von Behring, along with Römer, has also shown that immunity may be conferred on bovines by injection of tubercle bacilli of human origin, a striking argument in favour of the specific relationship of the two types of bacilli. These views, which have appeared since the appointment of the Commission, have only emphasised the need of further investigation.

The commissioners state that they felt it their duty to publish this interim report because the experimental results obtained by them are so striking.

The Commission was to inquire and report with respect to tuberculosis:—

(1) Whether the disease in animals and man is one and the same.

(2) Whether animals and man can be reciprocally infected with it.

(3) Under what conditions, if at all, the transmission of the disease from animals to man takes place, and what are the circumstances, favourable or unfavourable, to such transmission.

The first line of inquiry upon which the Commission entered was to ascertain the effects produced by introducing into the body of the bovine animal, either through the alimentary canal as food or directly into the tissues by subcutaneous or other injection, tuberculous material of human origin, that is, material containing living tubercle bacilli obtained from various cases of tuberculous disease in human beings, and how far these effects resembled or differed from the effects produced by introducing into the bovine animal under conditions as similar as possible tuberculous material of bovine origin, that is, material containing living tubercle bacilli obtained from cases of tuberculous disease in the cow, calf, or ox. More than twenty strains of tubercle bacilli have been employed, that is to say, the material taken from more than twenty cases of tuberculous disease in human beings. The effects produced were compared with those resulting from the injection of different strains of tuberculous material of bovine origin. In the case of seven of the above strains of human origin the injection of the human tuberculous material into cattle gave rise at once to acute tuberculosis, with the development of widespread disease in various organs of the body. In some instances the disease was of remarkable severity. In the case of the remaining strains the effects were less marked. The tuberculous disease was either limited to the spot where the material was introduced (this occurred, however, in two instances only, and these at the very beginning of their inquiry), or spread to a variable extent from the site of inoculation along the lymphatic glands with, at most, the appearance of a very small amount of tubercle in such organs as the lungs and spleen. Material, however, taken from the bovine animal thus affected and introduced into other bovine animals has, up to the present, in the case of at least five of these remaining strains, ultimately given rise in the bovine animal to general tuberculosis of an intense character. The disease thus set up in the bovine animal by material of human origin has been compared with that set up

in the bovine animal by material of bovine origin, and so far, both in broad, general features, and finer histological details, the two conditions have been found to be identical. The commission has, so far, failed to discover any character by which the one could be distinguished from the other, and the records contain accounts of the *post mortem* examination of bovine animals infected with tuberculous material of human origin, which might be used as typical descriptions of ordinary bovine tuberculosis.

There is no doubt that this interim report will be useful in strengthening the hands of local authorities, medical officers of health, and others, who have been struggling in difficult circumstances to obtain for the people a purer milk supply and food free from tuberculous contamination. As stated by the commissioners, the results obtained seem "to show quite clearly that it would be most unwise to frame or modify legislative measures in accordance with the view that human and bovine tubercle bacilli are specifically different from each other, and that the disease caused by the one is a wholly different thing from the disease caused by the other." G. D.

THE INTERNATIONAL ASSOCIATION OF ACADEMIES.

A COPY of the official record of the proceedings of the International Association of Academies at its plenary meeting on May 25, and of the proceedings of the section of science on the following day, has now been received from the Royal Society. The complete protocol of the meeting cannot yet be made up, because no report has yet been received of the proceedings of the section of letters; but we are informed that the proceedings on the last day of the general assembly in their plenary meeting consisted mainly of receiving the resolutions of the sections of science and of letters, and of certain complimentary resolutions with regard to the president of the meeting and to the Royal Society.

In the subjoined summary the foreign translations of the resolutions and details of the discussions have been omitted.

Wednesday, May 25.—After a few words of welcome from the president of the council (Sir M. Foster), Prof. Darboux (Secretaire perpétuel de l'Académie des Sciences) proposed Sir Michael Foster as president of the general assembly. The proposal was carried by acclamation.

The president opened the proceedings with an address, in the course of which he said:—

I accept with pleasure, though not without anxiety, the duties of the honourable though arduous post in which you have placed me, and trust that such short-comings as I may disclose may prove as little hindrance as possible to the success of our meeting. When we met in Paris our association was an infant of some fifteen months; it had just begun its dentition. It is now a lusty child of four years and more; it has cut all of its first set of teeth. I feel sure that you will join with me in the hope that its teeth will be used, never for secondary purposes, as aggressive weapons, but always for primary purposes, for carrying out the first stages of the digestion and assimilation of scientific knowledge and scientific thought into living active scientific flesh and blood. When I say "scientific" I use the word in the broad sense used by my illustrious predecessor in this chair, in his opening address at Paris, as meaning all knowledge which is exact and which can be verified. Though we call the two sections into which we divide ourselves, the one "scientific," the other "literary," we are none of us, I venture to say, satisfied with our nomenclature. We wish, all of us, that we could use names which should free us from the mere suspicion that there is even the taint of antagonism between the kinds of knowledge with which we have to deal.

The association began as a brotherhood of existing academies, but it has already advanced from brotherhood to parentage. At a meeting at Paris, the Royal Society of London excited much sympathy by its lone condition; while the delegates of most other countries represented the whole round of knowledge with which the association deals, those of England could speak of one part only. That sympathy provoked action, and led to the establishment of the British Academy for the Promotion of Historical, Philosophical and Philological Studies; and it has been one of the pleasant duties of my three years' term of office to bring about the admission of that academy into our fold.

One of the matters brought before the council of the association last year, concerning the relations of the association to proposals for international investigations requiring State aid, is placed on the agenda for the present meeting. The subject is one which demands our most anxious attention; may we be able to come to a decision which, while assuring the future usefulness of the association, may not tend to hamper scientific activity outside ourselves. On another matter, namely, the question whether the association should hold property, the council came to the conclusion that it was undesirable to attempt at present a definitive decision; and there the matter at present stands. The question does not come up for consideration at the present meeting, but it is one on which a decision must, sooner or later, be taken.

On the motion of Prof. Diels, Lord Reay was nominated vice-president.

Secretaries for the meeting were nominated as follows:—German, Dr. K. Krumbacher, Munich; French, M. A. de Lapparent, Paris; English, Dr. A. D. Waller, London.

The president proposed the following delegates as *Présidents d'honneur*:—Dr. Diels, Prof. Darboux, Count Balzani, Dr. Bakhuyzen.

Prof. Gomperz proposed that section ix. (4), (5), of the statutes be amended to read as follows:—Section ix. (4). The president (of the council) shall be appointed by the directing academy. Section ix. (5). The vice-president, who shall belong to the other section, shall be appointed in the same way. In the event, however, of the directing academy having only one section, the association shall entrust the appointment of the vice-president to another academy. The proposal was carried.

Prof. Darboux moved "That the initiation of any new international organisation, to be maintained by subventions from different States, demands careful previous examination into the value and objects of such organisation, and that it is desirable that proposals to establish such organisations should be considered by the International Association of Academies before definite action is taken." The resolution was carried.

Prof. Armstrong presented the draft report of the executive committee of the International Catalogue of Scientific Literature. Prof. Credner moved "That this meeting recognises the great value of the International Catalogue of Scientific Literature, and the importance of aiding the work by making its existence known, as well as of contributing to its efficiency and completeness by endeavouring to secure the indexing of scientific publications at the time of issue, in accordance with the plan adopted by the Royal Society." The resolution was carried unanimously.

Mr. Bryce announced that the British Academy was taking steps to publish a similar catalogue for philology, and the other branches of learning not included among the sciences of nature.

M. Boutroux gave a brief account of the work completed and contemplated in connection with the preparation of a complete edition of the works of Leibniz, and moved "That the association be requested to renew the commission to the three academies above named to prepare an edition of the works of Leibniz committed to them by the resolution of the association of April 18, 1901, and to request them to bring about, between now and the general assembly of the association in 1907, the publication of a critical catalogue, for which they have already collected the materials, of the Leibniz manuscripts." The resolution was carried.

The president proposed Vienna as the place of meeting of the next general assembly in 1907. The proposal was adopted unanimously.

Thursday, May 26.—Section of science. Secretaries were appointed as follows:—German, Dr. A. Riecke; French, M. A. de Lapparent; English, Dr. A. D. Waller.

Prof. Waldeyer presented, on behalf of the commission for investigating the anatomy of the brain, the report of the sitting of the committee of May 24.

Prof. Waldeyer moved the following resolution:—

"The several academies and societies represented in the association are recommended to bring before their respective Governments, or other appropriate authorities, in the name of the association, a proposal to establish a special institution or department of institutions for the investigation of the central nervous system, where such organisations are not already in existence, or cannot be created otherwise." The resolution was carried.

The following resolution, giving the committee power of cooption, was also carried:—

"That the Brain Commission have the power of cooption, as recommended in the report just received."

Prof. von Bezold moved "That a committee be appointed to consider the best means of bringing existing organisations into accord with the views of the International Association of Academies." This resolution was carried.

Sir A. Geikie, on behalf of the International Geological Congress, moved the following resolution:—"The International Association having received and considered a reference made to it by the International Geological Congress held at Vienna, 1903, resolves to ask the International Geodetic Association to take into consideration whether, and (or) in what way, it can undertake or promote international cooperation in the investigation of the following subjects:—

"Precise determination of levels in mountain chains subject to earthquakes, with the view of ascertaining whether such chains are stable or are undergoing movements of elevation or depression.

"Measurements of the value of gravity, with the object, so far as geological questions are concerned, of throwing light on the internal distribution of masses in the earth, and on the rigidity or isostasy of the terrestrial crust." The motion was carried unanimously.

Prof. Credner proposed that the committee on seismological investigations, appointed on the proposition of Prof. von Bezold, consist of the following members:—Prof. Schuster (chairman), Prof. Helmert, Prof. de Lapparent, Prof. Mojsisovics, Prof. Agamennone, Prof. A. P. Karpinski, Prof. W. C. Mendenhall. That the committee have power to coopt further members without votes. If a vacancy arise among the members of the committee, it shall have the power to fill up such vacancy subject to confirmation by the International Association.

Prof. Riecke moved the following resolution of the Academies of Göttingen, Leipzig, Munich, and Vienna:—

"That the International Association be requested to place the investigation of atmospheric electrical phenomena upon the list of its undertakings, and to arrange for carrying out observations upon atmospheric electricity for the period of two years at a large number of stations suitably distributed over the surface of the earth."

Prof. Schuster considered the matter to be in an experimental stage and hardly ready to be taken up by the association otherwise than as an experimental undertaking suitable for consideration by a committee, and proposed the following resolution, which was accepted by Prof. Riecke:—

"That a committee be nominated to prepare a plan for cooperation in investigations of atmospheric electricity, and to organise, if possible, such international cooperation for a period of two years."

Prof. von Bezold introduced the propositions of the Berlin Academy of Sciences relating to terrestrial magnetism, and moved "That the association nominate a special committee to consider as to the best methods of making accurate magnetic observations at sea with a view to carrying out a magnetic survey around a parallel of latitude." The motion was carried unanimously.

Sir David Gill presented the report of the Royal Society upon the undertaking for the measurement of the African arc of the 30th meridian, and moved "That the report of the Royal Society be adopted, with the following amendments, viz.:—

"That after the concluding words there be added:—

"(1) That the association notes with much satisfaction the sympathetic communication of the Imperial Academy of Sciences, St. Petersburg, on the subject of the arc of meridian, and recommends that diplomatic action be taken with a view to the extension of Struve's arc to Egypt.

"(2) The association expresses the hope that steps will be taken by the German Government under the advice of the Berlin Academy of Sciences to extend the arc along Lake Tanganyika, either by triangles extending across the lake or along its eastern coast as may be found the more desirable." The report was adopted with the additions proposed.

Prof. Fredericq presented the report of the late Prof. Marey on the work of the Institut Marey, and moved the following resolution:—

"The International Association of Academies approves the nomination of MM. Lippmann, Amagat, Charles Richet, Blix, Einthoven, Grützner, Langendorff, Schenck, Athanasiu as new members of the 'Association Internationale de l'Institut Marey.'"

"After having considered the report of the late Prof. Marey, dated May 5, 1904, on the work of the institute, the association congratulates the committee of the Marey Institute in having obtained in France recognition as being of public utility, and thus secured the permanence of this international scientific organisation. The association expresses its best wishes for the success of the scientific work undertaken at the institute." The resolution was adopted unanimously.

Other standing committees were appointed as follows:—For the investigation of terrestrial magnetism, Prof. von Bezold (chairman), Prof. Mascart, Prof. Palazzo, Sir Arthur Rücker, Lord Kelvin, Dr. Bauer, Prof. Liznar, General Rykacev, Prof. Wieckert, Dr. Paulsen.

For the investigation of atmospheric electricity, Prof. Exner (chairman), Prof. Arrhenius, Prof. Mascart, Prof. Schuster, Prof. Righi, Prof. Ebert, Prof. Riecke.

For both these committees resolutions were passed giving powers of cooption and for filling vacancies, similar to that passed in the case of the committee on seismology.

PROF. ADOLFO CANCANI.

AMONG the various sciences, the one which during the last few years has lost the greatest proportion of its workers is probably seismology. Von Rebeur-Paschwitz, M. S. di Rossi, Ehlert, Pacher, and Contarini have followed each other in quick succession, and to this death roll, with feelings of sorrow, we are called upon to add the name of the distinguished investigator Adolfo Cancani. Although connected with the University of Modena, Prof. Cancani's work was chiefly carried out while working with di Rossi at the observatory of Rocca di Papa, and later whilst engaged as an assistant at the Central Meteorological Observatory in Rome. At the former institution he introduced into seismometry the use of large and heavy horizontal pendulums the movements of which were recorded mechanically.

The first of these, which are probably the largest in the world, were 17 feet in height. The booms, made of T iron, were 10 feet in length, which at their outer ends carried in one case a block of marble and in the other a piece of pig iron. Beyond these heavy masses glass fibres recorded movements on a surface rotating at the rate of 60 cm. per hour. With this apparatus, all of which was home made, and cost but a few pounds sterling, Cancani obtained some striking seismograms.

In addition to taking this new step in seismometry, Cancani devised a photo-chronograph, various seismoscopes, and other instruments.

Although his investigations extended to several departments of earth physics, his chief works are those relating to seismology.

In July, 1903, at the Seismological Conference in

Strassburg, at which with his chief, Dr. Luigi Palazzo, he acted as a delegate for Italy, he brought forward a scale for seismic intensities which he followed by a paper on the possible relationship between small changes in latitude and the occurrence of large earthquakes. His last published paper relates to the advantages to be obtained from continuously moving high speed record receiving surfaces.

Seismologists throughout the world know Cancani's work, but those who were privileged to know him personally have stored up remembrances of an enthusiastic worker, gentle and persuasive in his speech, and with a kindliness of disposition of rare occurrence. He leaves behind a gap difficult to fill, a loss to a family, to a department, and to a new science. J. M.

NOTES.

Prof. George Darwin, F.R.S., has been elected president of the British Association for the meeting to be held in South Africa next year.

At the monthly meeting of the Royal Institution on Monday, the thanks of the members were returned to Dr. Andrew Carnegie for his donation of 1200*l.* to enable Prof. Dewar and Mr. R. A. Hadfield to prosecute their joint investigation on the physical properties of steel and other alloys at low temperatures; and to Dr. Frank McClean for his donation of 100*l.* to the research fund of the institution.

Prof. C. S. Sherrington, F.R.S., has been elected a member of the Imperial Academy of Medicine, Vienna.

It is reported that the University of Göttingen has awarded its Otto Wahlbruch prize, of the value of 600*l.*, to Prof. Wilhelm Pfeffer, professor of botany at Leipzig. The prize is awarded for the most important contribution to science during the past two years.

At the annual meeting of the Association of German Chemists, held at Mannheim on May 25, the Liebig gold medal for distinguished services in applied chemistry was presented to Dr. Rudolf Knietsch, of the Badische Anilin- und Soda-Fabrik, the discoverer of the so-called contact process of sulphuric acid manufacture.

On the recommendation of the Rumford committee, the American Academy of Arts and Sciences has awarded the Rumford medal to Prof. E. F. Nichols, of Columbia University, for his researches on radiation, particularly on the pressure due to radiation, the heat of the stars, and the infra-red spectrum.

Science announces the death of Mr. Frederick A. Walpole, botanical artist of the U.S. Department of Agriculture. He was considered the best plant artist in the United States, his drawings having been used to illustrate various reports published by the Department of Agriculture and the Smithsonian Institution, as well as the narrative of the Harriman Alaska Expedition.

A Reuter telegram from Frankfort-on-Main says that at the forty-fifth general meeting of the German Engineers' Association the Grashof medal, instituted in honour of the founder of the association, was unanimously conferred on the two pioneers of steam turbine propulsion, the Hon. C. A. Parsons, of Newcastle-on-Tyne, and M. de Laval, of Stockholm.

Through the efforts of an organisation known as the Edison Medal Association, a fund has been created to establish a medal to be known as the "Edison Medal," and the responsibility of annually awarding it has been entrusted to the American Institute of Electrical Engineers. A medal will be awarded this year by a committee soon to be selected from among the members of the institute.

Reuter's Agency learns that the expedition which left England in February under Lieut. Boyd Alexander for the forest region between the west coast and Lake Chad arrived in canoes at Ibi, 250 miles up the Binue River, in April. The explorers had already made some collections on the Binue, and intended landing at Ibi with the view of pushing north into Bauchi.

An official communication issued at Simla on May 17, and published in the *Pioneer Mail* of May 20, contains the following remarks:—"It has recently been stated in certain newspapers that the Government of India have rejected the offer made by Mr. Tata of a donation for aiding the foundation of an Institute of Science. This assertion is absolutely without foundation. So far from having rejected Mr. Tata's offer, the Government of India have promised a large subsidy to the scheme, and they have throughout the negotiations done everything within their power to facilitate its progress and aid the realisation of a project which has their fullest sympathy."

Dr. Friedrich Siemens, who died in Dresden a few days ago, was born in 1826 at Menzendorf, near Lübeck, and received his education in that town. In 1848, says the *Electrician*, he came to England to introduce his brother's, Dr. Werner Siemens, telegraphic apparatus. Afterwards he worked with his other brother, the late Sir William Siemens, and succeeded in applying the latter's regenerative principle to furnaces in combination with gaseous fuel, thereby making possible the production of open-hearth steel and the melting of glass by the continuous process in tanks. He also invented the regenerative gas burner and stove, and brought out numerous inventions connected with the glass industry.

A Reuter message from Queenstown states that Mr. Marconi is among the passengers on board the outward bound Cunard Steamer *Campania*. The daily newspaper which the Cunard Company have arranged to publish on board their four largest boats will be produced under Mr. Marconi's personal supervision. There will be a regular editor and printing staff on board each liner. The news received from shore will be supplied through Reuter's Agency. Mr. Marconi stated that he would have the *Campania* in communication with America on Monday through Cape Breton station, and would keep in communication with the Cornwall station until Wednesday night or Thursday morning.

Mr. J. Donovan, 1 Anstey Road, Denmark Hill, S.E., would be glad if psychologists or other investigators could send him information or references bearing upon the following points:—(1) A fairly representative list of animals, invertebrate and vertebrate, that make sounds in extreme pain or distress, although such sounds never serve to induce their fellows to help or relieve them, or even attempt to do so. (2) (*a*) Have any observations or experiments been made to show whether the sound or cry of pain or shock has any influence toward hindering or checking the oncoming of catalepsy or swoon in the animal producing the sound? (*b*) Are animals that do not possess means of sound production more subject to catalepsy from pain or shock than those which possess means of sound production?

Dr. Luigi Magri contributes to the *Atti dei Lincei*, xiii. (1), 9, some observations on the relation of the index of

refraction of air to the density. It appears that the index of refraction increases more rapidly under pressure than is consistent with the law $(n-1)/d=\text{constant}$, whereas the value of $(n^2-1)/(n^2+1)d$ is practically constant except at low pressures, where the observations could not be made with a great degree of accuracy.

DR. STÉPHANE LEDUC, of Nantes, has communicated to the French Physical Society a note on crystal formation, advancing the hypothesis that the phenomenon of crystallisation depends not only on the arrangement of the molecules in geometric forms, but also on the movement of these molecules through the liquid in certain regular and geometric directions. This hypothesis is based on the author's observations on crystallisation in liquids thickened by colloids.

IT is well known that two triangles in the same plane may be homologous in 1, 2, 3, 4 or 6 different ways at the same time, and that two tetrahedra may be homologous in 1, 2 or 4 different ways, it being assumed in either case that there are no common vertices. Prof. Luigi Berzolari contributes a note to the *Atti dei Lincei*, xiii. (1), 9, in which it is shown that in space of more than three dimensions two pyramidoids cannot have more than one centre of homology unless they possess common vertices or corners.

THE results of meteorological and magnetical observations made at Stonyhurst College Observatory during 1903 have been published in the usual concise form, with the exception of the valuable appendix containing the Malta meteorological returns. Father Sidgreaves states that the year will be known as the wet year, the rainfall being 11·8 inches above the annual average. Notwithstanding the unfavourable weather, the solar surface was observed on 207 days, and 141 plates have been added to the collection of stellar photographic spectra.

WE have received from the Deutsche Seewarte part xii. of *Ueberseeische meteorologische Beobachtungen*, containing carefully made observations, three times a day, at the following remote localities:—Marshall Islands (two stations), Nauru (lat. 26° S., long. 167° E.), Apia (Samoa), Tsingtau (lat. 36° N., long. 120° E.), and Rarotonga (Cook's Islands). With the exception of the latter station, all the observations were taken at the German colonies in the Pacific Ocean. It is worthy of note that the preparation of this very valuable work has been financially supported by the Colonial Department of the German Foreign Office.

CAPTAIN D. WILSON BARKER, in his presidential address to the Royal Meteorological Society, reviewed the past and present condition of ocean meteorology. The importance of this branch of science led to the international conference on meteorological observations at sea at Brussels in 1853, and to the establishment of the Meteorological Department of the Board of Trade by Mr. Cardwell in the following year, under the superintendence of Captain (afterwards Vice-Admiral) FitzRoy. He and Captain Maury in the United States (more especially the latter) are recognised as the most successful pioneers of ocean meteorology. Maury constructed wind and current charts for all oceans, copies of which were supplied gratuitously for the use of navigators in this country, and FitzRoy and his small staff at once set to work on them, and converted the pilot charts (which showed the wind directions numerically under each principal point of the compass) into graphical "wind-stars," and subsequently (about 1859) FitzRoy commenced the publication of a new series of monthly (instead of quarterly) charts, including wind-force and other data obtained from log-books collected by the Board of Trade Department. Other countries, especially France, Germany, and Holland, also pursued the subject vigorously; the Deutsche Seewarte published, among numerous other valuable works, an atlas of thirty-six charts of the Atlantic Ocean. In 1874 another international maritime conference was held in London, and was attended by representatives of all the principal nations. In this country the Meteorological Council, with the cooperation of the Hydrographic Office of the Admiralty, continues to devote untiring attention to this important subject. Captain Barker's able summary is contained in the *Quarterly Journal* of the Royal Meteorological Society for April last, and is illustrated by maps drawn on Flamsteed's projection, showing very clearly the principal meteorological elements, five or six maps being devoted to each of the great oceans.

WE have to acknowledge the receipt from the Field Columbian Museum, Chicago, of copies of three papers on mammals by Dr. D. G. Elliot, published last year.

WE regret to find that in the notice of Mr. Regan's paper on the classification of fishes in our issue of June 2 (p. 109), the Teleostei are stated to be derived from the Chondropterygii instead of from the Chondrostei.

ACCORDING to a well illustrated article in the March number of the *American Naturalist* by Prof. E. A. Andrews, the assumption that the breeding habits of the American crayfish are identical with those of its European relative proves to be incorrect, and it turns out that there are considerable differences in this respect between the two species. The second article in the same issue, by Mr. W. M. Smallwood, is devoted to the natural history of the bulla-like mollusc known as *Haminea solitaria*.

ALL recent experiments on keeping animals in menageries in the open air seem to point to the superiority over the old plan of confining them in close and narrow cages. In the report of the Zoological Society of Philadelphia for 1903, for instance, it is stated that the raccoons in the society's menagerie were recently placed in an open enclosure containing a tall tree with a cavity at the base, and a hollow log. With these natural retreats at hand, it is noteworthy that the raccoons preferred to pass their time in winter, even during most inclement weather, high up in the tree, some 40 or 50 feet above the ground. In the same report the importance of pathological investigations into the causes of death of animals dying in menageries is urged.

THE Australian Ornithologists' Union is to be congratulated on the completion of the third volume of its official organ, the *Emu*. Efforts are to be made in the immediate future to render this valuable journal more strictly scientific. The part before us contains a coloured plate of two species of honey-eater, which, although described many years ago, have never previously been figured.

ACCORDING to the report for 1903, there is a satisfactory and continuous increase in the amount of gate-money taken at the Giza Zoological Gardens, the receipts for that year being £1213 (Egyptian), against £1037 in 1902. An extremely interesting feature in the report is the notes on the habits of the numerous species of Nile fishes kept in the aquarium. From these it appears that the proboscis-fish (*Mormyrus kannume*) is chiefly nocturnal, and employs its long snout in probing about among stones for animal food.

Very remarkable is the statement that in the case of *Hydrocyon forskali* it was found advisable to keep a light burning near the tank in order to prevent the fish from injuring themselves by swimming violently against the glass walls.

An official publication issued at Colombo by the Government printer contains a summary of Prof. Herdman's report on the pearl oyster fisheries of the Gulf of Manaar, which may be considered as supplementary to the report on the same subject published by the Royal Society in November last, and already noticed in our columns. After referring to the condition and extent of the oyster-banks, the present report briefly points out the chief sources of injury to the molluscs, after which reference is made to the mode of formation of pearls, and the best methods of pearl-fishing. The report concludes with a series of recommendations, among which are comprised the substitution of dredging (in many instances) for diving, and the advisability of the appointment of a permanent naturalist.

An apparent instance of mimicry of a most remarkable type is recorded by Dr. A. Willey in *Spolia Zeylanica* for April (vol. ii., part v.). The attention of Dr. Willey had been directed by a correspondent to the striking resemblance presented by one of the Cingalese fishes commonly known as sea-bats (*Platax vespertilio*) to a decayed leaf, and soon after he had the opportunity of verifying this statement for himself. "I was walking," he writes, "along the reef in the company of a fisherman carrying a net when he espied a small fish, which he attempted to catch for me. I could not see what it was at first, but noticed that the man failed to bag it after several ineffectual attempts. The fish did not swim far away from the spot, but dodged about, baffling its pursuer. I approached and seized the net, whereupon I saw a yellow jak-leaf gently and inertly sinking to the bottom. This is no unusual sight, and I was about to turn away, when the leaf righted itself and darted off. Efforts were redoubled and the fish secured and sketched. . . . When a fish has a leaf-shaped and leaf-coloured body, and in addition the unique habit of toppling over and feigning death when pursued, it seems natural to conclude that it is a genuine example of protective resemblance."

Many of the visitors to Kew Gardens who take a special interest in the orchid houses will be interested to know that a revised edition of the "Kew Hand-list of Orchids" has been published, with the usual interleaved blank pages to facilitate the jotting down of notes. The increase in the number of genera, at any rate in the plants shown in the houses, has been very evident, and the catalogue gives a total of 220 for the collection.

The large proportion of economic questions which occupies the attention of the botanical departments in our colonies is well shown in the *Bulletins* (January, April) of the Botanical Department in Trinidad. A striking analysis of samples of sugar canes grown in Florida is quoted in an extract, in which no reducing sugar was found. The proportion of the sugars in canes is not only important from a commercial point of view, but as a purely scientific question is well worth investigating. The recommendation of carbon bisulphide as an insecticide affords evidence of the spread of scientific knowledge amongst planters. Other useful articles refer to prussic acid in cassava, rubber analyses, and treatment of "black pod" on cacao estates.

Prof. Eriksson returns to his mycoplasm theory, which asserts that rust fungi can hibernate in a protoplasmic form in the leaf-cells of the host, in a paper which appears in the *Transactions* of the Royal Swedish Academy of Sciences, vol. xxxvii., part vi., January. The investigations which were carried out by Dr. Eriksson and Dr. Tischler consisted in collecting the leaves of varieties of wheat which are liable to rust, and examining them both in late autumn and the following early summer, when no fungal mycelium could be observed, but in certain cells the authors distinguished a special dense accumulation of protoplasm, the mycoplasm. Later in July, intercellular fungal tubes were found which gradually developed into the ordinary hyphæ. The change from the mycoplasmic to the intercellular condition which is assumed still requires confirmation.

Mr. C. Fox-Strangways has prepared a second edition of his memoir on the Oolitic and Cretaceous rocks south of Scarborough (Geological Survey, price 4s. 6d.). More than twenty years have elapsed since the first edition was published, and opportunity has been taken of adding a series of pictorial views illustrating the fine cliff-sections, while the subject-matter is amplified throughout. The results of recent researches on the Speeton Clay are incorporated, and the author has dealt more fully with the interesting topics of scenery and denudation.

In an article on recent changes in the elevation of land and sea in the vicinity of New York City, and from a study of tidal observations on both sides of the Atlantic, Mr. G. W. Tuttle (*Amer. Journ. Sci.*, May) comes to the conclusion that the mean sea-level oscillates in an irregular manner, having an average period of about eight years. These oscillations appear to be largely due to changes in atmospheric pressure, and the resulting changes in wind velocities. In addition to the above movements, Mr. Tuttle finds that some ports show a more or less continuous rising of the sea relatively to the adjacent land, others a lowering of the sea-level in its relation to the land, and still others maintain a constant relation between the two. These last make it clear that, except for the periodic changes noted above, the sea does not change its level, and that the relative changes are due to land movements. Observations at New York City show that since 1875 the land has been subsiding at about 1·45 foot per century.

Messrs. Philip Harris and Co. have sent us a pamphlet giving a descriptive account of some new models and apparatus to be used in teaching the measurement of volumes, designed by Mr. S. Irwin Crookes.

Messrs. Watts and Co. have published for the Rationalist Press Association, Ltd., a pamphlet entitled "What to Read: Suggestions for the better Utilisation of Public Libraries," which contains the substance of an address delivered by Mr. John M. Robertson. Many useful hints to parents and librarians who wish to develop in children a love of reading and a regard for good books may be gathered from the address. The price of the pamphlet is fourpence.

With the growth of the Stassfurt industries and the increasing application of potassium salts in agriculture, a rapid method of estimating potassium has become a question of some importance. In the May number of the *Gazzetta*, N. Tarugi describes a volumetric method of estimating the element which depends on its precipitation in the form of the sparingly soluble persulphate. The method is accurate,

and can be carried out with great rapidity. Incidentally, the existence in aqueous solution at temperatures between 0° and 40° of four hydrates of potassium persulphate is established.

SOME experiments by Mr. K. E. Guthe, published in the April number of the *Physical Review*, show that fused steatite or soapstone can be used as a substitute for fused quartz in the production of fibres of very small elastic fatigue suitable for suspensions. The soapstone can be melted in a gas-oxygen jet, and very fine fibres are easily drawn out from the clear bead thus obtained. The elastic fatigue and tensile strength of these fused steatite fibres have approximately the same value as fused quartz fibres of the same dimensions. In the same journal Mr. J. H. Hart describes a continuous method of steam calorimetry which, with simple apparatus, gives results which compare very favourably with the best results obtained by the admittedly excellent continuous electrical method.

AN exhaustive account of investigations with the respiration calorimeter, by Messrs. Armsby and Fries, on the available energy of timothy hay has been issued as *Bulletin* No. 51 of the Bureau of Animal Industry of the U.S. Department of Agriculture. According to well known experiments of Rubner, different nutrient materials—proteids, fats, and carbohydrates—can replace each other in the animal metabolism, and "isodynamic values" can be deduced for the various nutrients. The authors question the applicability of Rubner's generalisation to herbivorous animals, and their experiments indicate that the digested matter of hay is not isodynamic with body tissue when the food supply is below the maintenance ration. It was found that only 63 per cent. of the metabolisable energy served to prevent loss of tissue, while 37 per cent. simply increased the heat production of the animal.

A VERY interesting paper dealing with the constitution of the ammonium compounds is contributed by Dr. J. C. Cain to the current volume of the *Memoirs and Proceedings* of the Manchester Literary and Philosophical Society (vol. xlviii., No. 14). To take examples, the author's suggested formulæ for ammonium chloride and ammonium hydrate are $H_3N=ClH$ and $H_3N=OH_2$, in which the chlorine and oxygen are respectively trivalent and tetravalent. The conception involved in this new formulation explains a large number of well known facts in a very satisfactory manner. It accounts for the difference between solutions of ammonia and of the alkaline hydroxides, and for the existence of isomeric quaternary ammonium salts. By means of it the formation of metal-ammonia compounds and of diazonium salts, the reduction of diazonium derivatives to hydrazine, and the process of diazotisation are all capable of simple representation.

OUR ASTRONOMICAL COLUMN.

SPECTRUM AND ORBIT OF δ ORIONIS.—Some very interesting results have been obtained by Dr. Hartmann in a research carried out at Potsdam on the spectrum and orbit of δ Orionis. The variability of the velocity in the line of sight—or, as Dr. Hartmann prefers to designate it, the "oscillation"—of this star was first discovered by Prof. Deslandres at Meudon, who determined the period as 1·92 days, and the orbit as very eccentric. Dr. Hartmann's results, however, do not confirm these conclusions, for he finds the period and the eccentricity to be

5d. 17h. 34m. 48s. ± 17s.

and 0·10334 respectively.

A striking feature on the spectrograms obtained is that the calcium line at λ 3934 ("K") is always sharp, whilst the other lines are characteristically hazy, and it *does not share in the periodic displacements of the lines caused by the orbital motion of the star.* Seeking an explanation of this anomalous behaviour, Dr. Hartmann has arrived at the conclusion that the absorption producing K does not take place in either of the components of the δ Orionis system, but in a separate "cloud" of calcium vapour situated somewhere between that system and our own. The distance of this cloud cannot be determined, but Dr. Hartmann suggests that its extent, perpendicular to the line of sight, might be approximately determined by the observation of the K line in stars situated in the same region and having "oscillations" similar to those of δ Orionis (*Astrophysical Journal*, No. 4, vol. xix.).

ANOMALOUS DISPERSION AND SOLAR PHENOMENA.—A further exposition of anomalous dispersion, and its action relative to solar phenomena, by Prof. W. H. Julius, appears in No. 10 (May 30) of the *Revue générale des Sciences.* After reviewing the current theories as to the sun's physical constitution, Prof. Julius proceeds to demonstrate that the "apparent" excessive speed of prominence variations, the abnormal solar spectrum photographed by Prof. Hale in 1894, the periodical variation of the solar radiation, the eleven-year period of solar activity, the connection between allied terrestrial and solar phenomena, and several other phenomena, may all be explained by considering the relative geometrical positions of the sun and earth, and the consequently variable distorted paths of the solar radiations. For example, he states:—"The eleven-year period may be the combined consequence of a progressive variation (not necessarily periodic) of the system of the surfaces of discontinuity and the periodic displacement of the Earth in regard to the rotating mass of the Sun."

PRIMITIVE CONDITIONS OF THE SOLAR NEBULA.—An interesting mathematical study of the conditions which probably obtained in the primitive solar nebula has been communicated to the Academy of Science of St. Louis by Mr. Francis E. Nipher, and is published in No. 4, vol. xiv., of the academy's *Transactions.* According to the equations developed by the author, it seems impossible that at the time when the planets were separating from the parent mass the nebula was wholly gaseous. The idea that the planets were formed from condensing swarms of meteorites is the only reasonable one which conforms with the numerical results obtained. It also appears that at the times when the moon separated from the earth, and Mercury from the sun, the respective parent masses must have been in the solid state, the sun having fused and become vaporised since the separation of Mercury. Further, it seems unnecessary, and even improbable, that the earth should ever have been in a state of fusion. By substituting the proper conditions in one of his general equations, Mr. Nipher finds that the isothermal 7000° C. is probably the one existing at the sun's surface at the present time.

INVARIABILITY OF SPARK AND ARC WAVE-LENGTHS.—In a paper communicated to No. 4, vol. xix., of the *Astrophysical Journal*, Messrs. Eder and Valenta describe the results they have obtained from a series of experiments performed in order to test the various theories as to the variability of wave-lengths, in arc and spark spectra, with the amount of vapour present or with the nature of the electric stimulus used.

As the result of his experiments, Prof. Haschek proposed, in a paper published in February, 1902, a system of *quantitative* analysis based on the measurement of the amount of "shift" a line experienced when varying quantities of the material under analysis were used. Taking most stringent precautions to eliminate subjective photographic effects, Messrs. Eder and Valenta have shown that these "shifts" do not really exist, and they state their conclusions in the following words:—(1) That at ordinary atmospheric pressure there exist no relative shifts between the arc and spark spectra as were said by Exner and Haschek to occur; (2) that there also exist no shifts in the spark spectrum which could be attributed to a reduced quantity of the element present in the vapour.

THE PROGRESS OF MARINE BIOLOGY.[1]

For some few years past the advances made by oceanography have been very marked, thanks to the rivalry which has grown up between different peoples. The English, the Americans, the Germans, the Belgians, the Scandinavians, and the Russians have made great efforts in this direction, while France, Italy, Austria and Portugal have not remained outside of the movement. Consequently this science in its principal features is already pretty well known.

But oceanography touches many departments of science, and amongst them marine biology is for the moment the least advanced, because it requires researches of a particularly difficult kind. It is to it that I have more particularly devoted my attention, and it is of it that I propose to speak this evening.

From the reports of many important expeditions, you are already well aware how universally distributed life is, even in the greatest depths of the sea; nevertheless, the means employed in this kind of investigation have been, as a rule, too primitive to furnish very complete results. In my own personal oceanographical work I have, for long, employed new means and methods, which attract different groups of marine animals, each according to its own characteristic instincts, and I have been able in this way to add to our knowledge of zoology.

It is not, however, enough to collect. We must also endeavour to penetrate the mystery of the laws which regulate life in the medium of the sea, so different in almost all respects from that of the air. For this the oceanographer requires the collaboration of the biologist and the physiologist.

Not unfrequently unexpected circumstances open to the observer new horizons, to be afterwards explored by science. It is thus that, finding myself among the islands of the Azores, to which my oceanographical researches have frequently conducted me, I assisted at the capture of a *cachalot*, or sperm whale, by the whalers of the country; simple peasants, who launch their well appointed whale boats the moment that the appearance of a fish is signalled by the look-out man, who is continually stationed on a little hill in their neighbourhood, and I have seen how these mammals go to the intermediate depths of the ocean in search of the great cephalopods which form their exclusive nourishment. When the *cachalot* in question came to endure the convulsions of death, its stomach rejected enormous fragments of the prey which it had captured during its last sounding.

It is in this way that I have recognised the existence of a fauna remarkable for the size and the number of its components, relegated to the large space which separates the surface from the great depths, but the organisation of which prevents its rising to the regions illuminated by the light of the sun, and probably also its descending to the bottom, when this lies beyond a certain depth.

What other groups of living animals inhabit these regions? We know nothing of them yet, but we may believe that they abound, because beings as powerful as these cephalopods require much nourishment.

So soon as I understood the importance of researches capable of throwing light on the life which exists in regions inaccessible to our ordinary means, I established on board of my ship all the equipments of a whaler, namely, three whale boats, each carrying a harpoon gun, several harpoons, a lance and a thousand metres of line, and I added to the complement of my ship an experienced Scottish whaler. The results of this organisation have left nothing to be desired. The cetaceans obtained already form an interesting collection, and their stomachs were abundantly furnished with these cephalopods.

In the Mediterranean, where previously the cetaceans had never been hunted, I have taken several individuals of the species *Grampus griseus*, *Orca gladiator*, *Globiceps melas*, and I lost a *Balenoptera musculus*. In the Atlantic Ocean I have taken several Globiceps and Grampus, as well as a very rare specimen of dolphin, *Steno rostratus*. I have also lost a cetacean of moderate size but of undetermined species.

[1] A Discourse delivered at the Royal Institution on Friday, May 27, by H.S H. Albert I., Prince of Monaco.

The attack of cetaceans, especially when they are large, causes the harpooneering novice an emotion which diminishes his *adresse*; and even for a good shot the use of the harpoon gun is very difficult when there is the least motion of the sea. A school of animals has been sighted. Their presence has been revealed by their blowing, or by the regular reappearance of their backs at a greater or less distance from the ship, which is then steered towards them. If the animals are of the species already mentioned, the movement of the propeller does not trouble them; on the contrary, they may almost always be seen to come and take up station near the stern as if retained by curiosity. But some species, and among them the *cachalot*, seem to distrust this neighbourhood, and care must be taken that they do not hear even the too marked sound of oars; indeed, in such cases it is preferable to use paddles rather than oars.

The animals have found in the depth a favourable hunting ground, and they do not leave it. They sound to this depth during a time which varies from ten to forty-five minutes, according to the species, and come to the surface again to breathe during four or five minutes. These alternations repeat themselves, sometimes for several hours consecutively, almost on the same spot, with occasional pauses, which seem to be those of repose. It is when the cetaceans appear in this way at the surface that the nearest whale-

Fig. 1.—Breaking up a Sp rm Whale.

boat should make every endeavour to come up with them before they again disappear, and so soon as one of them gives a sufficiently good presentation of the part of its body near the head, the harpooneer fires his shot. But this critical moment seldom arrives until after several hours of pursuit, even when the animals are full of confidence and allow the whalers to get well in amongst them. Most frequently, and in the most favourable circumstances, it happens that during the three or four seconds which the emergence of the animal at each of his eight or ten respirations lasts, the presentation is bad, or the movement of the sea has destroyed the aim; it is then necessary to wait until after the next sound.

If the animals sighted pursue a fixed route with any speed, it is useless to attempt the attack; it is impossible to come up with them because they are then on passage. Once I followed a large Balenoptera for six hours with my ship. He travelled about thirty miles in an absolutely straight line, which shows that the marine animals possess a sense of orientation more remarkable than that of the migratory birds, because these can always see the ground above which they travel.

At last, close to the boat, a powerful blow like a jet of

steam comes out of the water; the back of the animal emerges immediately afterwards; in the movement necessary to recover the horizontal position of its head, the dorsal fin appears and finally the lumbar region, which is much curved by the action of the tail, which determines the descent. It now proceeds for several lengths, hardly submerged, whilst the steersman, who can see the lighter-coloured portions of this immense body, and sometimes

Fig. 2.—Harpooning a Whale.

certain pools caused by the motion of the dorsal fin, steers the boat, driven by all the force of its crew, so as to cross the route of the cetacean. A fresh blow cuts the water, a black back presents itself at a distance of five or six metres, the shot is fired, and the eye can follow the harpoon with the attached line.

But at the first moment there is nothing to show that the animal has been touched. In a body of such size the arrival

Fig. 3.—Towed by a Grampus.

of sensation in the brain and the transmission of the will to the periphery require a sensible time. The success of the harpooneer is indicated by the rapid running out of the line, which very soon produces heat and a dense smoke in the bollard, round which a turn is taken in order to allow the harpooneer to regulate the run of the line according to the velocity of the cetacean and the direction which it follows. This is a very delicate moment for the safety of the whale-boat; nobody moves, and the turns of the line, carefully coiled in a receptacle, run out without a check. A second boat approaches in order to take the end of this line, when it is apparent that the thousand metres in the first boat will not be sufficient, and to add it to his own line. The running out is continued from this boat, and sometimes the three whale boats are rapidly cleared of their lines. But, with the friction which such a length of line offers, and to which the resistance of the boats towed has to be added, the cetacean reduces its speed very sensibly, so that there is no difficulty in maintaining it. Little by little the line is got back into the boats, and after various alternations the weakened animal advances more and more slowly, and close to the surface, where it is obliged to breathe more and more frequently.

Often many hours have passed before the favourable moment arrives for despatching the unfortunate victim and terminating the drama, and this is accompanied by the most serious circumstances of the whole enterprise. The exhausted animal stretches itself on the surface, almost motionless before the boat, where the harpooneer now holds a lance which has a considerable length, because it must pass through the whole thickness of the blubber and of the muscles before it reaches the vital organs. He approaches the animal by its side, so as not to be struck by the tail,

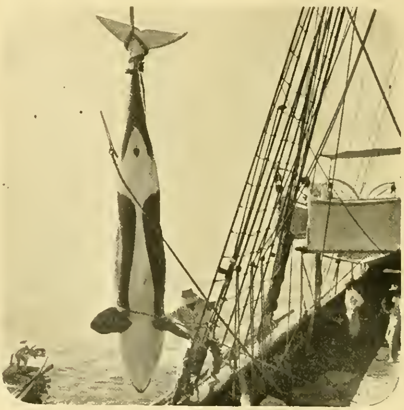

Fig. 4.—Hauling an Orca on board.

which may be thrown violently into the air so soon as the cetacean receives this new wound; but it is not always possible to avoid being struck by a fin, and especially in the case of large animals, this may wreck a boat. In spite of all the skill of the crew an accident of this kind may occur, and I could relate cases mentioned by various captains in which *cachalots*, old and solitary individuals, have seized and crushed between their jaws the boats which have attacked them. It has even been reported that two ships have been sunk by such animals in their fury, their enormous wedge-shaped head becoming in these circumstances a formidable ram.

When a cetacean of any size has been several times pierced, the red pool which spreads far over the sea gives the idea of great carnage. In fact the cetaceans contain a very large amount of blood, and before the last hour, when they lose it in torrents, they have already left behind them a red track of eight or ten miles in length over which they have towed the boats.

I have said that apart from the interest which each species of cetacean offers of itself (and it appears that some of them are hardly known at all), it is in the first place the contents of their stomachs which occupy us. The species which I have taken differ much in the nature of their prey, and their mouths are armed correspondingly. The *right whale*

is content to absorb the *plankton* composed of extremely small animals, which in some regions form a compact mass, a real cloud; and in order to keep out objects too large to pass down its very small throat, its jaws are furnished with the well known and valuable *whalebone*, which acts as a sieve.

The Grampus, the Globiceps, and the Cachalot penetrate to a depth probably much greater in search of cephalopods,

FIG. 5.—Skeleton of an Orca.

and they possess a dentition specially organised for seizing the gelatinous flesh of the cephalopods. The scars which they bear over the whole of their bodies are evidence of the energy with which their victims defend themselves with their suckers, often armed with formidable talons.

The Orca, provided with a more compact dentition, pursues the dolphins, of which it makes scarcely more than three or four mouthfuls, showing thus a remarkable power of digestion.

The dolphins themselves are more eclectic, and I have found in their stomachs several species of fish as well as cephalopods, but in both of them the characteristics special to great depths are wanting.

The principal object which I had in view in capturing the cetaceans, the knowledge of the beings living in the abysses, has been realised by the acquisition of a certain number of new and very rare cephalopods. Some of these are gigantic, and amongst them may be cited *Lepidoteuthis Grimaldii*, one of the most remarkable animals of the sea on account of its considerable size, and also because, though it is a cephalopod, it possesses scales like a fish.

The more we know of marine biology, and the more we

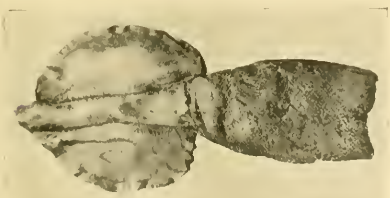

FIG. 6.—Part of the Fin of a Gigantic Cephalopod.

learn from it of the links which connect the creatures spread over our planet, of the interpenetration of types, such as that shown by Lepidoteuthis, as well as of the vital force, the great power of reproduction, the number of individuals in certain species, and the high antiquity of other forms, we seem to be justified in imagining that the sea may have been the cradle of organic life when the cooling of the atmosphere determined the precipitation of the waters.

THE ROYAL OBSERVATORY, GREENWICH.

THE report of the Astronomer Royal to the Board of Visitors of the Royal Observatory, Greenwich, was read at the annual visitation of the observatory on Saturday last. Some of the results and observations described in the report are referred to in the subjoined abstract.

The progress made in the observation of the reference stars for the astrographic plates (for which more than 10,000 stars are to be observed, three times above and twice below pole) has been so satisfactory that it is expected that sufficient observations of all the stars will have been secured by the end of 1905, at which date it is proposed to terminate the observations. The catalogue of the astrographic reference stars will thus be completed in nine years, a year earlier than was originally proposed.

After consultation with Prof. Albrecht, it has been arranged to apply the correction for latitude deduced by him from the provisional discussion of the international series of observations to all observations of north polar distance year by year, commencing with 1902, Prof. Albrecht having arranged to communicate his results as soon as practicable after the end of the year. This correction has been applied to all the north polar distances for 1902 and to the planetary observations for 1903, and is now being applied in the star ledgers.

Provision having been made for the comparison between theory and the Greenwich meridian observations of the moon from 1750 to the present time, the discussion of the longitude of the moon 1750–1901, compared with revised tabular places, has been undertaken by Mr. Cowell on a plan devised by him, which enables the complex calculations to be done in a very economical manner, the lunar day being adopted as the unit of time. Mr. Cowell has published explanations of his methods of analysis of the moon's errors, together with some of the results obtained, in the *Monthly Notices* of the Royal Astronomical Society, November, 1903, to May, 1904.

The 28-inch refractor has been used throughout the year for micrometric measurements of double stars. The total number of double stars measured during the year is 512; of these, 178 have their components less than $1''.0$ apart, and 85 less than $0''.5$. The wider pairs consist of bright stars with faint companions, stars of special interest, and stars from Struve's catalogue which have not been measured within the last thirty years.

The occulting shutter has been used in the photography of Neptune and its satellite with the 26-inch refractor, and a good series of photographs has been obtained during the opposition of 1903–4. During the year the following photographs have been taken:—with the 26-inch refractor, 58 photographs of Neptune and satellite, 22 photographs of 10 double stars, 13 photographs for adjustments; with the 30-inch reflector, 117 photographs of 40 minor planets, 27 photographs on 27 nights of comet *c* 1903, 17 photographs on 12 nights of comet *a* 1904.

The photographs of comets have all been taken with short exposures, usually four on each plate, and are for the purpose of determining positions. Four exposures have also been given on each photograph of a minor planet, the object being to obtain accurate determinations of position on three or four nights for each planet during the opposition. In addition, the following photographs with long exposures have been obtained:—of comet *c* 1903, comet *a* 1904, the great nebula in Andromeda, and the Pleiades.

Considerable progress has been made with the measurement of the long series of photographs of Eros taken during the opposition of 1900–1. The measures have been made with the new micrometer described in a communication to the Royal Astronomical Society on May 13. With the magnification in use the probable error of the bisection of a perfectly defined speck is $\pm 0''.020$; the probable accidental error of a single measure of an image of Eros is found to be $\pm 0''.067$ on an astrographic plate, and $\pm 0''.040$ on a Thompson plate.

Owing to the error inherent in the star-images, the probable error of a position of Eros derived from a number of measures of four images on one plate is not nearly so small as the above measures suggest. Comparison of the positions of Eros for October 26 and 27 with the tabular places of M. Loewy's ephemeris gives a probable error of

$\pm 0''.082$ and $\pm 0''.045$ for photographs taken with the two instruments respectively. With the parallactic factor of October 26 and October 27, it results that two of the Thompson plates at the beginning of the evening compared with two at the end are sufficient to give the solar parallax with a probable accidental error of $\pm 0''.016$. We may therefore expect an adequate result for the somewhat arduous measurements and reductions involved.

No observations were made with the spectroscope during the year.

The solar activity increased considerably during the year ending May 10, the sun being free from spots on only 25 days, as against 190 in the previous year. The mean daily spotted area for 1903 is nearly six times as great as for 1902; still, as yet, the rate of increase is not so great as in the corresponding periods of the two preceding cycles. The greatest outburst of the year commenced on 1903 October 5, with the appearance at the east limb of the sun of a group of spots much larger than any seen since 1898 September. Several fine groups have appeared since.

The principal results for the magnetic elements for 1903 are as follows:—

Mean declination	16° 19'·1 West.
Mean horizontal force	4·0132 (in British units). 1·8504 (in Metric units).
Mean dip (with 3-inch needles)	67° 0' 51".

The magnetic disturbances in 1903 have shown a marked increase in number and extent. There were five days of great magnetic disturbance and seven of lesser disturbance. Traces of the photographic curves for these days will be published in the annual volume. The calculation of diurnal inequalities from five typical quiet days in each month, selected in concert with M. Moureaux and Dr. Chree, has been continued.

The mean temperature for the year 1903 was 50°·2, or 0°·7 above the average for the fifty years 1841–90. During the twelve months ending 1904 April 30, the highest temperature in the shade was 87°·5 on July 14. The highest temperature in the Stevenson screen was 84°·2, and in the observatory grounds 85°·0, on the same day. The lowest temperature of the air recorded in the year was 23°·8 on January 1. During the winter there were forty-three days on which the temperature fell below 32°·0, being thirteen days below the average number.

The mean daily horizontal movement of the air in the year ending 1904 April 30 was 300 miles, which is 18 miles below the average of the preceding thirty-six years. The greatest recorded movement was 796 miles on February 13, and the least 69 miles on January 23. The greatest recorded pressure of the wind was 36 lb. on the square foot on September 10, and the greatest hourly velocity 43 miles on September 10 and 11.

During the year 1903, Osler's anemometer showed an excess of sixteen revolutions of the vane in the positive direction N., E., S., W., N., excluding the turnings which are evidently accidental.

The number of hours of bright sunshine recorded during the twelve months ending 1904 April 30, by the Campbell-Stokes instrument, was 1361 out of 4472 hours during which the sun was above the horizon, so that the mean proportion of sunshine for the year was 0·304, constant sunshine being represented by 1.

The rainfall for the year ending 1904 April 30 was 35·42 inches, being 10·88 inches greater than the average of the fifty years 1841–90. The number of rainy days was 182. The rainfall during 1903 was 35·54 inches, the heaviest ever recorded at Greenwich during the calendar year. The summer months in particular were very wet, more than 16 inches being recorded in June, July, and August, viz. 6·07 inches registered in June, 5·27 inches in July, and 4·82 inches in August. The greatest fall registered at Greenwich in a single day for many years past, viz. 2·46 inches, occurred on July 23. In 1904, January and February were wet months, so that the total fall from 1903 March 1 to 1904 February 29 was more than 37 inches.

The determination of the longitude of Potsdam by Prof. Albrecht and Dr. Wanach was completed in July. The result, which has been recently published by Prof. Albrecht, leads to an indirect determination of the longitude of Paris which is in close accordance with the results obtained by the Greenwich observers in 1902.

The revision of Groombridge's Catalogue for 1810, in connection with the Greenwich Second Ten Year Catalogue (1890), and the determination of the proper motions of about 4000 stars from Groombridge's observations, compared with recent Greenwich observations at an interval of about eighty years, have now been completed under Mr. Thackeray's supervision, and the results will be published without delay.

HIGHER SCIENTIFIC EDUCATION IN FRANCE.

At one of a series of education conferences held recently at the École des Hautes Études Sociales in Paris, Prof. Appell, of the University of Paris, delivered an important address on the present facilities provided in France for higher instruction in the various branches of science, paying special attention to institutions established for this purpose in Paris. The address is published in the *Revue générale des Sciences* for March 30 last.

The address opened with a general historical account of the evolution of current estimates of the importance of scientific education of university standing and of the stages in the growth of French institutions in which such higher instruction is now given. Prof. Appell then recapitulated concisely the actual organisation of higher scientific teaching in existing schools and colleges in France, and supplemented his survey by indicating various improvements he considered desirable. Agreeing with British men of science, he urged that students must from the beginning of their work be led to avoid "une tendance fâcheuse à se contenter d'apprendre et de répéter la parole du maître," and that the object of all teaching should be to develop the scientific spirit and to encourage in the students a desire to apply to everything the methods of research.

The succeeding section of the discourse was concerned with scientific education in its relations to the practical applications of science to the needs of industry. A very liberal interpretation was given to the expression "technical" school, and the term was used to include such institutions as the schools of pharmacy, schools of mines, and agricultural colleges. Prof. Appell pleaded for a differentiation of the functions of the numerous establishments in which higher scientific education is being given, and in speaking of the work of all these technical schools, emphasised the great importance of insisting upon a good basis of general scientific knowledge on which to rest all instruction in technology. The absence of a due co-ordination of the work of existing scientific institutions in Paris was then pointed out, and a scheme outlined indicating the changes and developments desirable in order to realise "une union féconde entre la science et les applications."

The concluding subject of the address appeals in an especial manner to readers of NATURE. In it Prof. Appell indicated the increasing need in modern times for every great nation to encourage scientific research liberally. He condemned the danger most likely to exist in a democracy of judging the importance of a chair or lectureship at a university by the number of students it attracts; the test ought rather to be, it was pointed out, the number of discoveries which can be associated with a given laboratory or the amount of research work done in connection with it. The fallacy of disparaging new results in science because at the time they appear only of theoretical interest was demonstrated by reference to the researches of Newton and Pasteur. Suggestions were then made as to how to encourage the best students of science to devote a number of years to research work, and also in the direction of ensuring the most scientific and economical arrangement of buildings intended for research work in science. As an example, Prof. Appell referred to one of the needs of the University of Paris. This want was described as the creation on a large site, distinct from the Sorbonne, of an institute of chemistry, where laboratories for, and advanced instruction in, inorganic, organic, biological, and technical chemistry could all be found under the same roof, instead of being situated, as they actually are, in three distinct parts of Paris.

The concluding portion of the address is a powerful plea for the adequate endowment of research of all kinds. As Prof. Appell showed, it is in research laboratories that advances in industrial processes are really made, and it is a wise economy to encourage the foundation of such institutions. The discourse should have an immediate beneficial effect on the further supply of higher scientific education in France, and it is probable that the lessons drawn by Prof. Appell from Charlottenburg and from similar American technical institutes will serve to demonstrate to French statesmen the importance of the subject with which the address deals with such ability.

SOFT CHEESE-MAKING IN THE HOME COUNTIES.

IN the rapid increase of grass land during the last thirty years, farming in the Home Counties has seen a remarkable change. The exhaustion of land by the too frequent growth of cereals during the period of high prices, and the fall in the price of corn since, made corn, as the main product of farming, unprofitable to cultivate in part of this district. The land has been laid, or in too many cases has been allowed to lay itself, down to grass, and, instead of corn, milk has now become the principal agricultural product. This change is most noticeable within a circle having London for its centre and a radius of thirty or forty miles, for milk is both bulky and perishable, and railway charges and time in transit both desiderate its production near the great centre of consumption.

It must not be supposed that the greater part of this area is particularly well suited for grazing purposes. On the contrary, unlike the west country, or the polders of Holland, where second year's grass has all the appearance of an old pasture, it takes twenty years to produce a good pasture on the London-clay or Boulder-clay soils. It was one of the most mischievous effects of the high price of corn in the middle of the last century that the good old pastures, which formed perhaps one-third of most of the farms, were broken up. Besides, even when a good pasture has been produced, the climate is not humid enough in summer to produce an abundant growth; it is rare to get more than one cut of meadow-hay in a season, and the aftermath generally provides indifferent grazing. Per acre, the returns in milk are therefore not great. No doubt the output might be greatly increased by introducing the Danish system of dairy-farming, *i.e.* growing a succession of green tillage crops for feeding the cows instead of pasturing them, but the scarcity of cheap labour, which is the most serious drawback to intensive farming in the neighbourhood of London, prohibits the practice of this system.

The time of year when the milk production is greatest is the month of May. From observations made in Essex last year it was found that the yield of milk in May was about 20 per cent. greater than in the winter, while during the summer it fell off to an equal extent as the quality of the grazing deteriorated. The consumption of milk in London, on the other hand, fluctuates but little, and farmers must therefore limit their sale to their minimum output, and are unable to take advantage of the flush of milk in the spring to increase their returns.

It is clear that dairy-farmers require some outlet for this surplus milk. To give it to the calves and pigs is to utilise it for a purpose for which foods purchased at half the price per food unit would serve equally well. Taking everything into consideration, the use to which it could most profitably be put is in the making of soft cheese, for which there is a ready demand whenever placed on the London market. Soft cheese-making requires none of the expensive appliances and little of the storage that are necessary for hard cheese-making, and there is nothing to hinder its being carried out on any farm. But it needs knowledge and skill, and this is a subject of agricultural instruction, therefore, which the education committees in the Home Counties could most usefully provide.

Very opportunely, a little handbook on soft cheese-making has recently appeared,[1] for the preparation of which the authors, in virtue of their experience at Reading and Wye, are particularly qualified. First and foremost they lay stress on the need for cleanliness in the handling of milk, for, as they point out, taints are far more noticeable, because further developed, in soft cheese than in the milk from which it is made. But even in the production of milk for sale, reform in the matter of cleanliness is badly needed. Nowhere probably in the whole of Europe are cows kept in a filthier condition than in parts of England and Wales, and it is not unknown to find in milk a sediment of hair, dust and dung, which points to dirty cattle. In Holland and Hungary the cows are regularly groomed, and this is not only done to prevent contamination of the milk, but also because the cows, being made more comfortable, do better and give more milk. Besides dirtiness of the cows, contamination of milk is due to a variety of causes—dust blowing in an ill-kept, windy byre, neglect of the milkers to wash their hands before milking or to put on a clean over-jacket, the use of impure water for washing pails and churns, &c., and it must be remembered that not only is such contamination an injury to the public, but it is sometimes the cause of loss to the farmers themselves when milk is returned to them as unsaleable. Short courses of instruction in the handling of milk for farmers and farm hands are badly needed. It may be doubted whether, without systematic science training, all the sources of bacterial contamination of milk can ever be guarded against, and it is to be urged that the county education committees should also provide for instruction in dairy bacteriology for those who, though a limited few, will, when distributed through the farming community, gradually spread the knowledge of the possible sources of bacterial contamination.

Once the principles of cleanliness have been mastered, the making of soft cheese is merely a matter of practice and attention to the details which are admirably set out in this little handbook. Of the sorts of cheese for making which directions are given, Bondon, Coulommier and Cambridge may be specially recommended, because they are milk cheeses and will consume the whole of the surplus milk on a farm, and because they need no ripening, and therefore require no storage accommodation. For the first-named especially there is known to be a good demand in London. They can all be made at any farm where a room capable of being kept at a uniform temperature is available, by the purchase of 5*l.* worth of appliances.

This is only one of the directions in which education committees in the Home Counties can directly aid the new style of farming, and in the neglect of which they will lose a splendid opportunity for usefulness. Greater productiveness of the land by more rational manuring, more economical feeding of dairy cattle, and improvement in the milk-producing qualities of dairy herds, are also needed to make the industry fairly profitable. In the writer's experience the majority of farmers feel their difficulties far too acutely to reject any means of improvement which are provided in a form of which they can make practical use.

INHERITANCE OF PSYCHICAL AND PHYSICAL CHARACTERS IN MAN.[1]

IN his Huxley lecture, Prof. Karl Pearson gives the result of a prolonged investigation into the inheritance of the mental and moral characters in man (see NATURE, vol. lxviii. p. 607, October 22, 1903). His main conclusion is a remarkable one; it is that "the physical and psychical characters in man are inherited within broad lines in the same manner, and with the same intensity. . . . We inherit our parents' tempers, our parents' conscientiousness, shyness and ability, even as we inherit their stature, fore-arm and span."

Great as are the obstacles in the way of a precise determination of the power of heredity in the physical sphere, those in the psychical are far greater. This arises partly from the difficulty of obtaining trustworthy evidence in the

[1] "On the Inheritance of the Mental and Moral Characters in Man, and its Comparison with the Inheritance of the Physical Characters." The Huxley Lecture for 1903. By Prof. Karl Pearson, F.R.S. Pp. 179–237. (Published by the Anthropological Institute of Great Britain and Ireland, 3 Hanover Square, London, W.)

latter case, partly from the absence of any definite standard of measurement. Prof. Pearson, with characteristic ingenuity, has found means of overcoming both kinds of difficulty, and has succeeded in showing that for the inheritance of all observed traits, whether belonging to the "mental" or "bodily" category, the slope of the "regression" line closely approximates to the same value, viz. 0·5. Considering the extent to which the personal element must needs enter into any estimate, however careful, of comparative ability or character, the uniformity shown by the author's tables is far greater than might have been expected. Some, indeed, may incline to the opinion that he proves too much, for if the influence of heredity is supreme alike in the mental and moral, and in the physical domain, what room is left for the action of teaching, training, discipline, and the environment generally, influences which the common experience of mankind has held to be of importance? Prof. Pearson partly meets the difficulty by reminding us that "the average home environment, the average parental influence is in itself part of the heritage of the stock." This is true enough, but scarcely covers the whole ground, because a great deal of the average environment is not parental.

Still, however firmly we may be convinced of the power of education to foster desirable qualities of whatever kind, there can be little doubt of the significance of the author's figures with regard to the material on which education and experience have to work. From these considerations there emerges a practical conclusion of the highest importance. "Intelligence," says Prof. Pearson, "can be aided and be trained, but no training or education can *create* it." "The mentally better stock in the nation is not reproducing itself at the same rate as it did of old; the less able, and the less energetic, are more fertile than the better stocks. No scheme of wider or more thorough education will bring up in the scale of intelligence hereditary weakness to the level of hereditary strength. The only remedy, if one be possible at all, is to alter the relative fertility of the good and the bad stocks in the community."

ANTHROPOLOGICAL NOTES.

WE have frequently directed attention to the splendid work done by Mr. Clarence B. Moore in his archæological investigations in Florida. In the second series of the *Journal* of the Academy of Natural Sciences of Philadelphia, part iii. of vol. xii. is devoted to a memoir on certain aboriginal mounds of the Florida central west coast, and, like Mr. Moore's previous publications, it is sumptuously illustrated. Perhaps the most interesting find is a fish-spear of native copper; this is a unique record for Florida. There is little doubt that the ancient coppersmith had arrived at the knowledge that hammering the metal gave it stiffness. Numerous copper ornaments were found, such as pendants and ear-plugs, some of the latter being decorated with symbolic designs. None of the skulls from this district exhibited cranial flattening, though it was extensively practised on the north-west coast of Florida. In the latter district were found ceremonial vessels in which large holes had been made before the firing of the clay, but they do not occur along the central west coast. The mounds on the Apalachicola River yield forms of burial similar to those prevailing along the north-west coast of Florida. Ceremonial vessels, "killed" by a basal perforation and by holes throughout the body, made before the firing of the clay, were found in considerable numbers; the ware is most inferior in quality, as might be expected of vessels purposely made for interment with the dead.

There was a spirited discussion in the *American Anthropologist* during 1903 concerning the origin of the sheet copper found in the Florida mounds. Mr. J. D. McGuire contended that it owed its origin to European influences, but the whole weight of evidence and experience was against him.

There is immense variety in the basketry of the native tribes of America as regards form, technique, decoration and the materials employed, and our colleagues of the United States fully realise the importance of studying the designs with which so many baskets are ornamented while there is yet an opportunity of discovering their significance. We have several times referred to this subject; the latest publication of this kind is an admirably and copiously illustrated memoir, by G. T. Emmons, on the basketry of the Tlinget, in the *Memoirs* of the American Museum of Natural History (vol. iii. part ii.). The accuracy with which designs have been preserved and transmitted through so many generations is evidence of the conservatism of primitive peoples; most of the patterns of the past may be seen in the work of to-day, but the modern tendency to produce new figures is born of the rivalry in trade. The old characters are being combined to form attractive though meaningless figures, and so symbolism in design will gradually be lost. In existing circumstances the future of basketry is not difficult to foresee; the younger generation learns to read and write, but seldom learns to weave, and so the time is not far distant when Alaska must follow in the footsteps of all the basket producing countries. It is fortunate that, in the meantime, we have such an admirable piece of work as Mr. Emmons has produced, as he has saved from oblivion the meaning of many patterns and designs.

The following ingenious method of ethnological investigation adopted by Mr. E. Thurston, superintendent of the Government Museum, Madras, is worth rescuing from the oblivion of the report for the year 1902–1903. "In the inquiries concerning manners and customs, a novel and eminently effective method of arriving at the truth concerning tribal ceremonials was resorted to, marriage and death ceremonies being acted in the form of theatricals in which each performer at the real ceremony was represented by a member of the class concerned. In this way the interest was thoroughly sustained, and the fatigue, which soon supervenes among illiterate people when they are interviewed, was avoided. Moreover, apparently trivial but really important points of detail were clearly brought out in a manner which is impossible by mere oral examination. I have myself had to play the part of maternal uncle, and, as representing the *swami*, to receive the obeisance of the mock bride. The leading *rôle* of corpse at a funeral was played either by an elderly man or by a clay votive figure purchased from a local potter. The pupils of the eyes of these figures are not painted in till they are taken to the temple, where *puja* is done to them, as it is the painting of the eyes which endows them with life."

In the report on the administration of the Government Museum of Madras for the year 1902–1903, Mr. E. Thurston writes:—"Two tours were made in the course of the year. During the first of these the physical measurements of the jungle Uralis and Sholagas of the Coimbatore district were examined by myself, and their visual acuity, colour vision, &c., by Dr. W. H. R. Rivers, of Cambridge. It took many months before confidence was restored among these primitive folk, who, as a report records, 'could not understand why the measurements of the different organs of their bodies were taken; perhaps to reduce or increase the size of their bodies, to suit the different works which they were expected to do near London.' They believed, too, that the variously coloured wools, given to them for selection, were for tying them captive with. . . . A prolonged halt was subsequently made at Coimbatore, where the Kaikolans, Oddes, Okkiliyans, &c., were investigated. The Oddes, unfortunately, all have the title Boyan added to their names, and a fatal rumour was spread among them that the object of my visit was to transport the strongest among them to South Africa, to replace the Boers who had been killed in the war. My evil eye was cast on them, and they refused to fire a new kiln of bricks for house construction till my departure from their midst."

In appropriate yellow guise is published a new illustrated quarterly review called *Buddhism*, by the International Buddhist Society, at the Hanthawaddy Printing Works, Rangoon. The first article of the second number gives an account of the election and installation of the Taunggwin Sayadaw as Thathanabaing of Upper Burma. This functionary is the patriarch or ecclesiastic head, who is supreme in all matters connected with religion, and next to the king is the person most held in esteem. It is eight years since the last Thathanabaing died, and the people were as sheep without a shepherd, and feared that the Government would never exert its royal prerogative and elect a successor; but to their intense relief and satisfaction this was done in November, 1903. The review contains an

interesting paper on the Pali and Sanskrit texts by Prof. T. W. Rhys Davids. Judging from the other articles, this new journal should perform a useful service in clearly pointing out the true nature of Buddhism. In common with other religions, Buddhism has many extraneous local beliefs and practises grafted upon it from which it requires to be pruned. The foreigner too often does not distinguish between these two elements, and from this point of view alone the review will perform a useful task.

The brilliant work done by Prof. G. Elliot Smith on the mammalian brain is acknowledged by all anatomists, and they will eagerly look forward to the memoir (which is based on the examination of more than 400 human brains, and of an almost equally large series of simian cerebral hemispheres) that is shortly to be published as vol. ii. of the "Records of the Egyptian Government School of Medicine." A summary of the main conclusions is published in the *Anatomischen Anzeiger,* Band xxiv. p. 436. The most striking result of this investigation is the demonstration of the fact that the sulci called "calcarine" in most human and all simian brains respectively are not strictly homologous. The so-called "calcarine fissure" of the apes is a complete involution of the whole mesial part of the area striata, fossa striata occipitalis, whereas the similarly named furrow in the human brain consists in most cases of anterior and posterior parts which are genetically distinct, the anterior part being the anterior limiting sulcus of the mesial area striata, sulcus præstriatus, and the posterior part a mere depression in (not a complete infolding of) the mesial area striata, sulcus intrastriatus.

Those interested in human craniology are aware that Prof. Sergi, of Rome, has inveighed against the cephalic index, and has introduced a new nomenclature for describing skulls by inspection. Several English anthropologists recognise that the cephalic index has its uses and abuses, but there is an indefiniteness about Prof. Sergi's nomenclature, which besides is somewhat complicated, that prevents them from adopting the latter to the exclusion of the former method. As a matter of fact, they employ both systems, but only make use of the simpler terms introduced by the Italian anatomist. Dr. F. Frassetto has now applied Prof. Sergi's method to the anthropoid apes, and the following are his main conclusions. The skull of the adult chimpanzee is byrsoides rotundus, the less fully grown skull is byrsoides cuneatus; there is progressive reduction in the cephalic index, 88 to 70. The skull of the adult gorilla is byrsoides asciformis, while that of the young is ellipsoides cuneatus; there is a similar reduction in the cephalic index during growth, and the average breadth is less. On the whole the skull of the orang-utan is sphæroides and platycephalus; the cephalic index varies from 91 to 75. Thus the Asiatic anthropoid tends to preserve the primitive brachycephaly, while the African forms, especially the gorilla, become dolichocephalic. The author directs attention to the essential brachycephaly of Asiatic man and the dolichocephaly of African man. Pithecanthropus, however, which he describes as byrsoides asciformis, "is a fossil form of African anthropoid found in Asia." This short but suggestive paper will be found in the tenth anniversary volume of the *Atti della Società Romana di Anthropologia* (Rome, 1904.) A. C. H.

INTERNATIONAL OCEANOGRAPHY.[1]

THIS first instalment of the observations of the international scheme of deep-sea investigation proves conclusively the unique value of the undertaking, launched amid many difficulties, both for the advancement of the purely scientific interests of marine zoology and meteorology, and for their practical applications to matters of fisheries and weather forecasting. It contains the numerical results of the observations made during August, 1903, by ships sent out specially by no less than ten countries—Belgium, Germany, Denmark, England, Finland, Holland, Norway, Russia, Sweden, and Scotland. The classification is that of the council, and we may ignore any question as to the international relations of Sweden and Norway, Finland and Russia, or England and Scotland, and congratulate ourselves on the fact that so many nationalities have been found to agree to meet on neutral territory and to engage in a uniform scheme of scientific research, as of happy omen.

The *Bulletin* is divided into four sections, A, B, C and D. Section A consists of a table of observations of the condition of the atmosphere as to its temperature and movement, and of the condition of the surface water as to its temperature and salinity. The distributions disclosed by the data are shown graphically on two maps, one on a scale of 1 : 18,000,000, which includes the whole area, the Baltic, the North Sea, the North Atlantic and the Arctic, and another, on a scale of 1 : 6,000,000, giving the North Sea, the English Channel, and the Baltic entrance, in more detail. The maps contain much that is of supreme interest, but it is greatly to be regretted that advantage has not been taken of the skill and enthusiasm of the commanders and officers of ships crossing the Atlantic in lower latitudes to extend the maps into the region in which the explanation of facts they show is to be looked for.

In Section B we find the observations of temperature and salinity at various depths. The salinities are determined by chlorine titration of water samples collected, and from these and the observed temperatures the specific gravities *in situ* have been computed. These tables profess a high degree of accuracy—temperatures to hundredths of a degree, salinities to two places of decimals, and specific gravities, in some cases, to six places—but it seems hardly necessary to inquire whether all the figures given are significant or not, or, if they are, whether it is worth while to trouble about the necessary refinements when observations taken from ships, the positions of which are scarcely known to within a mile or two, on any day during a month, are lumped together as if they were absolutely simultaneous. For in the end we obtain a series of sections which is absolutely invaluable. Discussion of these sections is impossible in the space available here, and in any case it will be better delayed until further bulletins provide material for comparison. We may, however, instance as of special interest the sections across the Færöe-Shetland Channel furnished by the Scottish Fishery Board, and the parallel section from Bergen to Iceland of the Danish and Norwegian observations. We are now in possession of a number of sections in this region for different years, and the constant change in the relation of the northward and southward moving streams is a phenomenon of ever-increasing interest.

Section C contains the results of gas analyses of a number of the samples collected by the German, Dutch, and Danish vessels. It is to be hoped that the other nationalities will join in this very important part of the work. The last section is devoted to tables showing the distribution of plankton.

It is worth noting that four of these bulletins will constitute one volume, for which the subscription is one pound.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Mr. Beck, master of Trinity Hall, has been elected Vice-Chancellor for the ensuing academical year.

Prof. Howard Marsh has been approved for the degree of Master of Surgery.

The Vice-Chancellor has published to the Senate a resolution unanimously passed by the Association of Chambers of Commerce of the United Kingdom supporting the recent communication from the council of the Royal Society, and urging that steps be taken to "ensure that a knowledge of science is recognised in schools and elsewhere as an essential part of general education."

The special syndicate appointed for the purpose report in favour of the university granting a diploma in mining engineering to members of the university who have completed six terms' residence, and have pursued an approved course of theoretical and practical study in the subject.

Prof. Ewing's Rede lecture, on the structure of metals, will be delivered in the anatomy and physiology lecture room on June 11 at 11.30 a.m.

Prof. W. H. Perkin, F.R.S., of Manchester, has been appointed an elector to the chair of chemistry and to the Jacksonian professorship.

Dr. L. Humphry, Dr. S. West, Dr. W. Hale White, and Dr. J. Rose Bradford, F.R.S., have been appointed examiners in medicine; Dr. Handfield-Jones and Dr. Herman, examiners in midwifery; Mr. Clinton Dent, Mr. Edmund Owen, Mr. Mansell Moullin, and Sir Hector Cameron, examiners in surgery for medical degrees.

Two portfolios of valuable drawings, illustrating ophthalmology and otology, have been presented to the university by Dr. Ole Bull, of Christiania. They will be exhibited at Oxford next month by Prof. Clifford Allbutt.

Sir William H. White, K.C.B., F.R.S., will open the new workshops, laboratories, &c., at the Merchant Venturers' Technical College, Bristol, on Wednesday, June 29.

At a meeting of the council of University College, London, on Monday, June 6, Dr. Gregory Foster was appointed principal of the college as from September 1 next, in succession to Dr. Carey Foster, who had intimated his intention not to seek re-election on the expiration of his office at the end of August. Mr. Tansley was appointed lecturer in plant anatomy for a term of three years. Mr. E. C. C. Baly was re-appointed lecturer in spectroscopy for a term of three years.

It is announced in *Science* that the Bill appropriating 50,000*l*. for the erection of a building for the College of Agriculture at Cornell University has been signed. From the same source we learn that Mr. Eugene N. Foss has given 10,000*l*. to the University of Vermont for the million dollar fund which the graduates of that college are trying to raise to mark the centenary of the institution; and that the will of the late Mr. Solomon Loeb, of New York City, has given 2000*l*. for the Chemical Laboratory of the New York University, 2000*l*. for the Hebrew Technical Institute, and 1000*l*. to the American Museum of Natural History.

In a copy just received of the Johns Hopkins University *Circular*, we notice a feature that might well be copied by other institutions of a similar kind, viz. the publication of "Notes in Biology," edited by Prof. Brookes, and "Notes in Mathematics," edited by Prof. F. Morley. A very useful purpose is served by the publication of such "notes" in a university journal, which would hardly be a suitable medium for the detailed exposition of the results of lengthy researches. In the biology notes the body cavities and nephridia of the Actinotrocha are discussed by Dr. R. P. Cowles, while the mathematical notes deal with linear correspondences, the orthic cubic curve, and the construction of quadric polarity in space.

The North of England Education Conference, which met for the first time in Manchester in January, 1903, and held its second meeting in Leeds in the early part of the present year, is to meet on the next occasion in Liverpool. The first meeting of the executive committee appointed to make arrangements for the next meeting of the conference was held at Liverpool on Friday, June 3, when Alderman W. Oulton, chairman of the Liverpool Education Committee, was appointed chairman of the executive committee, and Mr. E. M. Hance and Mr. W. Hewitt were appointed joint secretaries. It was decided that the conference should be held on Friday, January 6, and Saturday, January 7, of next year, and a general purposes subcommittee was appointed to make arrangements as to the subjects for papers and discussion.

A public meeting of residents of the central part of Calcutta was held on May 4, the *Pioneer Mail* states, with the object of promoting the advancement of scientific and industrial education among Indians. In opening the meeting, Mr. Norendro Nath Sen remarked that a lakh of rupees was required annually, to be devoted to scholarships for deserving students to enable them to proceed to England, America and Japan for the study of the industries and arts of those countries. The marvellous progress of Japan, the speaker continued, is due entirely to education in this direction. The people of India cannot be too grateful to the Government of India for providing scholarships, but the Government should not be allowed to carry the burden alone. It is left to the residents to develop and complete the work begun by the Government, and it is for this purpose that the movement has been started. The formation of local associations such as this one in Calcutta should have an excellent effect on scientific and technical education in India.

It has for some time past been a matter of comment that while American universities, and in several cases foreign ones—such as the University of Leyden—have frequently devoted considerable sums of money to the endowment, and in some instances to the separate publication, of scientific transactions, our English universities have not only been unable to subsidise the publication of researches, but have in most cases even failed to give their staffs sufficient leisure for the efficient prosecution of original work. The appearance of a paper by Prof. Karl Pearson on mathematical contributions to the theory of evolution, bearing on the title-page "Department of Applied Mathematics, University College, University of London—Drapers' Company Research Memoirs," is significant in more ways than one. It represents the fact that, probably for the first time, a City company has given an endowment of 1000*l*. to a university for the furtherance of research pure and simple, and further it indicates that mathematical research is at last beginning to receive public recognition. The present paper deals with the theory of contingency and its relation to association and normal correlation.

The attention of the reader who is interested in the teaching and development of mechanics and mathematics is directed to an important address by Prof. A. Sommerfeld, of Aachen, on "The Scientific Results and Aims of Modern Applied Mechanics," of which an abridged translation, by Mr. R. M. Milne, has appeared in the *Mathematical Gazette*. The address is a powerful statement of the now prevalent view that in teaching mechanics the foundations must be securely laid by systematic experimental work on the part of the students themselves, for whom suitable facilities must be generously provided; it is also a plea for a closer attention on the part of mathematicians to the problems of practical mechanics. In this country these doctrines have long been associated with the name of Prof. Perry, F.R.S., and one of the latest phases in the movement is the reform of the teaching of elementary mathematics. Prof. Sommerfeld states that most of the German high schools now possess richly equipped laboratories for research and instruction in mechanics, and that the value of such work is generally recognised and greatly appreciated. He also describes the nature of some of the experiments and investigations that are carried out in these laboratories.

It is satisfactory that there seems to have been a general agreement among the speakers at a recent meeting of the National Association of Manual Training Teachers—held to discuss the references to manual training in schools in the reports of the Mosely Educational Commission—as to the need in all schools for practical work conducted on scientific lines. Mr. Mosely said that the broad-minded way in which American engineers tackled the problems brought before them was what first excited his interest in the system of education in the United States. Mr. Mosely agrees with Prof. Armstrong that it is the fourth "R" which makes all the difference between the educational results in the United States and in this country. American teachers are right in giving more attention to the teaching of how to reason in a scientific manner than is common in English schools. Prof. Armstrong, who also spoke at the meeting, deprecated the erection of what he called "a magnificent metal workshop here and a magnificent wood workshop there," and said a large supply of costly machinery of one kind is unnecessary. A variety of occupations rendered possible to the boys is what is wanted, and the manual training thus provided should be related to local requirements.

SOCIETIES AND ACADEMIES.

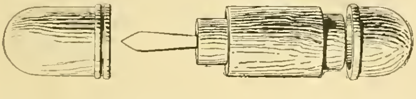
LONDON.

Royal Society, March 17.—"On the Effect of a Magnetic Field on the Rate of Subsidence of Torsional Oscillations in Wires of Nickel and Iron, and the Changes Produced by Drawing and Annealing." By Prof. Andrew **Gray,** F.R.S., and Alexander **Wood,** B.Sc.

May 5.—"Experiments on a Method of Preventing Death from Snake Bite, capable of Common and Easy Practical Application." By Sir Lauder **Brunton,** F.R.S., Sir Joseph **Fayrer,** Bart., F.R.S., and Dr. L. **Rogers.**

Although this paper is a joint one, the authors mention that each had a different share in its production. The whole research may be regarded as the natural outcome of the work begun in India nearly forty years ago by Fayrer; the instrument employed was designed by Brunton and the experimental work was carried out by Rogers.

Of late years a great deal of important and instructive work has been done by Fraser, Calmette and others in regard to the preparation of antivenins, the injection of which will preserve life in animals poisoned by snake venom. This method of treatment, however successful it may be, is open to the objection that its application is very limited, as it can only be employed in places where the antivenins can be stored ready for use. In order that any method of preventing death from the bites of snake poison should be of much practical utility, it must be one which can be constantly at hand when wanted and easy of application by unskilled persons, and as it is especially needed by very poor people, such as the natives of India, it must also be very cheap. In connection with this paper, an instrument which seems to promise good results was shown at the Royal Society. It consists simply of a small lancet about



half an inch long with a hollow wooden handle, in which crystals of permanganate of potash are contained. The way in which it is proposed to apply the permanganate is, that anyone bitten by a snake should at once tear a strip from a turban, shirt or any other article of clothing, and tie it as quickly as possible above the bite. A cut should then be made with the lancet over the site of the bite so as to convert the puncture made by the snake's tooth into a small wound. Into this the crystals of permanganate of potash, moistened with saliva if necessary, are to be rubbed. Permanganate of potash as an antidote to snake poison was first used by Fayrer in 1869; it was shown by Wynter Blyth in 1877 to be a complete chemical antidote to cobra venom, when mixed *in vitro*, and his results were confirmed by Brunton and Fayrer in 1878. The anti-vivisection law prevented them from carrying these experiments further at the time, but their continuance in this country has now been rendered possible by Dr. Waller's invention of a method of giving chloroform continuously for forty-eight hours or more. By means of this instrument Captain Rogers has been able to test the effect of permanganate of potash applied in the manner already described on rabbits and cats. Five out of six animals experimented upon survived after the injection of cobra poison, and a similar number survived after the use of Daboia poison. These experiments, which were entirely carried out by Captain Rogers, are very satisfactory, inasmuch as they show that the utility of permanganate of potash is not confined to one class of venom, but that it acts equally well with the venom of all kinds of snakes. The results obtained five minutes after the injection of the poison were as good as half a minute after injection, so that although very rapid absorption occurs during the first few seconds, it seems probable that absorption soon becomes slow from local effusion, and that sufficient time would thus be afforded for the application of the proposed antidote. Further experiments will be carried on by Captain Rogers in India, and if they prove as successful as those which he made in this country, it is proposed that lancets,[1] with full directions for use, should be sold at a very cheap rate at all the post offices in India, in the same way as packets of quinine are sold at present. If the plan of treatment should prove efficacious, it will be a great pleasure to Sir Joseph Fayrer to see the fruition of the work which he began forty years ago.

Chemical Society, May 18.—Prof. W. A. Tilden, F.R.S., president, in the chair.—The action of nitrosyl chloride on pinene: W. A. **Tilden.** It is shown that the yield of this compound by the usual processes is improved by using a mixture of equal quantities of *d*- and *l*-pinenes. For the regeneration of pinene from the nitrosochloride, methylaniline is recommended in place of aniline.—The electrolytic estimation of minute quantities of arsenic: H. J. S. **Sand** and J. E. **Hackford.** The authors recommend the use of lead electrodes for the estimation of minute quantities of arsenic, as their application permits of a simplification of previous methods.—The action of sodium methoxide and its homologues on benzophenone chloride and benzylidene chloride, part ii.: J. E. **Mackenzie** and A. F. **Joseph.**—The bromination of phenolic compounds: J. T. **Hewitt,** J. **Kenner** and H. **Silk.** It is shown that when one molecular proportion of bromine acts on phenol, the character and proportions of the products obtained vary with the conditions under which the reaction is carried out. Absence of water and presence of a strong mineral acid favour the formation of *p*-bromophenol, whilst sodium acetate in a glacial acetic acid solution diminishes the quantity of para-derivative formed.—The decomposition of the alkylureas. A preliminary note: C. E. **Fawsitt.** An investigation of the velocity of decomposition of the alkylureas with acids shows that the hydrolysis is indirect, and is effected as a secondary reaction of the acid with the alkylammonium cyanate first formed.—The formation of periodides in nitrobenzene solution, part ii., periodides of the alkali and alkaline earth metals: H. M. **Dawson** and Miss E. E. **Goodson.** In general, these iodides have properties similar to those of the potassium derivative already described, and the experimental data indicate that enneaiodides of the type $M'I_9$ or $M''I_{18}$ probably represent the highest limiting type of periodides.—The action of ozone on ethane. Preliminary note: W. A. **Bone** and J. **Drugman.** The authors have obtained ethyl alcohol by the interaction of ethane and ozone at 100°. The paper gives an account of the method and apparatus employed.—Caproylthiocarbimide: A. E. **Dixon.** A description of this substance and of a number of its derivatives is given.

Royal Meteorological Society, May 18.—Capt. D. Wilson Barker, president, in the chair.—The principal causes of rain: the Hon. F. A. Rollo **Russell.** The chief causes of rain are only four, but several of these are often in cooperation. These causes may be briefly described as follows:—(1) the forced ascent of moist air by the slopes of mountains; (2) a mass of air invading rather suddenly another mass moving from an opposite direction and maintaining its flow below the opposing current which it displaces; (3) the ascent of more or less moist air through heavier and colder air to a height where condensation of vapour takes place, increased radiation of heat towards space, and often electrical developments producing further condensation, increase of temperature, and renewed ascent with the same results; (4) the mixture of currents of air from different directions.—On the observations of rainfall at the Royal Observatory, Greenwich, in the years 1815 to 1903: W. C. **Nash.** The author has made a full inquiry into the circumstances relating to the early history of the register, and has drawn up an authoritative table of rainfall for the long period of eighty-nine years. The average annual rainfall is 24·36 inches, and the number of rainy days 157. The greatest fall was 35·54 inches in 1903, and the least fall 16·38 inches in 1858. During the five months January to May, no monthly fall exceeding 4·37 inches was recorded, but in the remaining seven months there were twenty-four falls exceeding 5 inches. Light falls of rain are spread principally through the nine months January to September, with a decided preponderance in spring.

[1] The lancets were made by Messrs. Arnold and Sons, West Smithfield.

Anthropological Institute, May 24.—Prof. W. Gowland in the chair.—Mr. E. F. **Martin** exhibited a large collection of native objects which he had obtained during his residence in northern Nigeria. The exhibit, which was of great interest, comprised specimens of musical instruments, weapons, leather and brass work and pottery, chiefly manufactured by the Hausas.—The Rev. C. T. **Collyer** delivered a lecture on Korea and its people, which he illustrated by numerous lantern slides. Mr. Collyer, during his twenty years' residence in the country, had unrivalled opportunities of observing the Koreans, and in his lecture he gave a valuable account of their manners, customs and architecture. His slides illustrated native types and buildings, and he also explained by diagrams the plan of the Korean house, with the theoretical arrangements for separation of the sexes, their system of counting and their alphabet, which is simplicity itself, consisting of only twenty-five letters, in marked contrast to the elaborate system of ideography in use amongst the Chinese and Japanese.

Linnean Society, May 24.—Prof. S. H. Vines, F.R.S., in the chair.—Anniversary meeting. The following officers were elected:—President, Prof. W. A. Herdman; treasurer, Mr. Frank Crisp; secretaries, Dr. D. H. Scott and the Rev. T. R. R. Stebbing. The president devoted the greater part of his address to considering the life-work of Linnæus and his claim to the gratitude of later workers. The president then presented the Linnean gold medal to Dr. A. Günther.

Physical Society, May 27.—Mr. J. Swinburne, vice-president, in the chair.—The law of action between magnets and its bearing on the determination of the horizontal component of the earth's magnetic field with unifilar magnetometers: Dr. C. **Chree**. Starting with the general formula for the action between two magnets perpendicular to one another, in Lamont's first position, the author discusses how observations should be combined when the higher terms usually neglected in magnetometer reductions are taken into account.—On the ascertained absence of effects of motion through the æther in relation to the constitution of matter on the FitzGerald-Lorentz hypothesis: Prof. J. **Larmor**. In consequence of recent misapprehensions (*cf.* D. B. Brace, *Phil. Mag.*, March), the argument on this subject, as given in "Æther and Matter" (1900), is briefly re-stated. The absence of effect of convection, to the first order, was demonstrated by Lorentz. Absence of effect to the second order of the ratio of the velocity of convection to that of radiation has now been experimentally established, as regards optical interference with long path, by Michelson; as regards mechanical action on a charged electric condenser, by Trouton; as regards double-refraction, by Lord Rayleigh and by Prof. Brace. This suggests strongly a complete correspondence in detail between the material system connected with the earth's motion and the same system at rest in the æther, so that their internal relations are indistinguishable. Theoretically such complete correspondence, up to the second order, exists, involving the FitzGerald-Lorentz shrinkage, provided a purely electrical constitution of matter (as regards its physical relations) is granted, but apparently not otherwise. Thus it is held that these phenomena point consistently in that direction.—On coherence and re-coherence: Dr. P. E. **Shaw** and C. A. B. **Garrett**. In a paper in the *Phil. Mag.* (March, 1901), Dr. Shaw described a method of investigating coherence by measuring the forces required to sunder the cohered surfaces. It was there shown that forces of the order of 1 dyne were required for a copper-copper contact of two single wires. Further, there seemed to be evidence of a change of state at the place of coherence, possibly orientation of the particles at the contact. In the present paper the authors follow the same method of investigation, adducing evidence that coherence can be explained, and only explained, by Lodge's original theory of fusion, and further establishing the after-effect, whether orientation or otherwise, mentioned in the former paper.

Cambridge.

Philosophical Society, May 16.—Dr. Baker, president, in the chair.—Note on the effect of a magnetic field on the vibrations of an atom containing six corpuscles placed at the corners of a regular octahedron: Prof. **Thomson**. The Zeeman effect for a single corpuscle vibrating about its position of equilibrium is to split up the spectral line corresponding to its free vibration into a triplet, the difference between the frequencies of the extreme lines of the triplet being He/m, in a field of strength H. Measurements of the magnetic separation of lines in the spectra of various elements show that different lines may experience different separations. The object of this note is to describe a model atom the vibrations of which would not all be affected in the same way by a magnetic field. It is shown that if six corpuscles are arranged at the corners of an octahedron their vibrations will under the magnetic field be split up into three triplets; in one of these the separation of the frequencies will be normal, *i.e.* He/m, while in the other two the separation will only amount to *half* the normal value.—The effect of screening on ionisation in closed vessels: A. **Wood**. Previous experimenters have shown that the so-called spontaneous ionisation in closed vessels is in part due to a radiation from the walls of the vessels. The experiments described go to show that this radiation consists of two kinds, (*a*) a secondary radiation excited by a penetrating radiation from without, and (*b*) an intrinsic radiation probably due to a true radio-activity of the material. The former predominates in vessels of iron, zinc and tin; the latter in vessels of lead and aluminium.—Quasi radio-activity produced by the point discharge: S. A. **Edmonds**. A metallic body becomes quasi radio-active when points are made to face it, and both points and body are connected to the terminals of a Wimshurst machine, and the discharge passed in dusty air. When caused to pass in the outside air, or in air freed from dust either by settling or by filtration through glass-wool, no effect is obtainable. All metals act equally well, while the points do not become at all active. This quasi activity is considered to be due to the dust particles in the air trapping the ions present during the discharge and forming a film of them on the surface of the body.—Magnetic deflexion of the negative current of electricity from a hot platinum wire at low pressures: G. **Owen**. The paper contains an account of experiments made to obtain some information with regard to the mechanism of the discharge at low pressures. The experiments lead to the conclusion that the carriers of the current are mainly corpuscles at all temperatures. When proper precautions are taken, about 90 per cent. of the carriers are deflected by a magnetic field corresponding to that required to deflect particles for which the ratio e/m is 10^7.—Some photoelectric effects: W. M. **Varley**.—Note on the atomic weight of bismuth: R. H. **Adie**. In this note the author gave his determinations of the atomic weight of bismuth, which confirm the results of Classen and fix the value at about 208·8.—Note on compounds containing an asymmetric nitrogen and an asymmetric carbon atom: H. O. **Jones**. The investigation of the formation of compounds containing an asymmetric nitrogen atom from an optically active tertiary amine was undertaken in the hope that the two possible isomerides would be formed in unequal quantities and separable by ordinary means. This expectation has been realised for the union of methyl-*l*-amyl-aniline with allyl and benzyl iodides.—The spatial configuration of trivalent nitrogen compounds: H. O. **Jones** and J. P. **Millington**. The paper describes the results of some experiments made with the view of obtaining evidence as to the configuration of trivalent nitrogen compounds, by attempting to resolve compounds in which the valency of the nitrogen should not change during the process. Methyl-ethyl-aniline-sulphonic acid was prepared and its brucine salt submitted to fractional crystallisation, but without effecting any resolution, and similarly with the dextro-camphor-sulphonate of benzyl-phenyl-hydrazine. It is therefore concluded that the three groups attached to the trivalent nitrogen atom are normally situated in the same plane with it.—Relations among perpetuants: A. **Young**.—On the proportion of the sexes among the Todas: R. C. **Punnett** and W. H. R. **Rivers**.

Edinburgh.

Royal Society, May 2.—Prof. Geikie in the chair.—In a paper on the date of upheaval which caused the twenty-five-feet raised beaches in central Scotland, Dr. Robert **Munro** went carefully into the evidence, and gave

reasons for fixing the date of upheaval subsequent to the Bronze age and anterior to the Roman occupation.—Dr. R. H. **Traquair** exhibited a skull of the great extinct ox (*Bos taurus*, var. *primigenius*), and certain remains of reindeer, which had been found in the grounds of Dundas Castle, Dalmeny. The skull was very large, and indicated a great stretch of horns.—Prof. A. Crichton **Mitchell** gave certain preliminary results he had obtained on the rate of convective loss of heat from a surface exposed to a current of air. A thin strip of platinum foil formed the one branch of a Wheatstone bridge, which was constructed so as to be able to carry very powerful currents. The current through the strip was strong enough to raise it to the temperature of incandescence, and was measured accurately on a galvanometer placed suitably in the circuit. The strip was enclosed in a tube through which a blast of air was drawn by means of a large fan worked by a gas engine. The velocity of the air was measured directly in each case. The experiment consisted in finding the resistance of the strip, and therefore its temperature, for given values of heating current and velocity of air. It is evident that for moderate velocities of air current the strip will, for a particular value of electric current passing along it, be cooled more or less according as the air current is greater or smaller. The results so far obtained indicated that even in still air a large part of the cooling was due to convection. It was hoped that the experiments would lead to important information as to the relative amounts of convection and radiation when a surface was cooling in the air.

May 16.—Sir John Murray in the chair.—Dr. J. **Halm** read a paper on a cosmic theory of the diurnal and long-period changes of terrestrial magnetism and their possible connection with seismic phenomena and the displacement of the earth's axis of rotation. On the assumption that the atmosphere is a feeble electric conductor set in oscillation by the thermal and gravitational action of the sun and moon, an expression was obtained for the diurnal variation of magnetic potential. This contained as a factor the variation in height of a mass of air. But on the assumption that the air was in an average state of convective equilibrium, the principles of thermodynamics led to the result that this time variation in height was proportional to the time variation of the air temperature at the earth's surface. Hence was deduced the formula $V = a \sin 2\phi d\theta \ d\lambda$, where V is the magnetic potential, ϕ is the latitude, λ the longitude, θ the temperature, and a a constant. The equipotential curves so obtained showed a remarkable resemblance to Schuster's curves deduced from magnetic observations, the main difference being a lag in longitude (equal to time) of the real curves as compared with those deduced from theory. The next step in the argument was to consider the possible strains which might result from this diurnal variation in magnetic distribution, and the conclusion was that such strains would cause a slight bulging on the side next the sun. This one-sided tide agreed with the indications of the horizontal pendulum as found by Ehlert, and with the recent measurements of change of direction of plumbline. It was easy to see that the change in declination of the sun would give rise to seasonal effects, and the periodicity indicated for various latitudes agreed in a suggestive manner with the seasonal curves of seismic activity in these latitudes. By an application of the same principle of convective equilibrium, Dr. Halm showed that the daily oscillation of the barometric pressure could be represented as the sum of two terms, of which one depended on the change of temperature from the mean and the other on the second differential coefficient of the temperature at the surface. The constant factor multiplying the latter term is the same along a latitude parallel, at least to a first approximation, but the multiplier of the former term depends on the character of the locality according as it is maritime, continental, or mountainous. The general theory advanced brought into connection not only meteorological and magnetic phenomena, but also seismic activity, change of latitude, and displacement of the earth's axis, and all as a result of solar radiation acting on the earth's atmosphere. It was natural to search for the eleven-year period in these variations. A careful tabulation of Omori's recent statistics of earthquakes in Japan from the earliest recorded cases showed an undoubted eleven-year period, and gave another argument in favour of the idea that seismic activity was influenced by magnetic changes. The paper touched upon several other astronomical and meteorological problems.

PARIS.

Academy of Sciences, May 30.—M. Mascart in the chair.—The chemical effects of light. The action of hydrochloric acid upon platinum and gold: M. **Berthelot.** Pure gold and platinum are slowly attacked by fuming hydrochloric acid in the presence of light; control experiments in which these metals were treated with hydrochloric acid and kept in the dark gave no metal in solution. In the presence of manganese chloride the amount dissolved was nearly doubled.—Study of the solubility of silicon in silver. On a variety of crystallised silicon soluble in hydrofluoric acid: H. **Moissan** and F. **Siemens.** Silicon is much more soluble in fused silver than in lead or zinc. The crystallised silicon found in the solidified metal contains a certain proportion of an allotropic variety of silicon which is soluble in hydrochloric acid. The experimental results are expressed in the form of a curve, showing the relation between the total silicon dissolved as a function of the temperature, and also of that portion which is soluble in hydrofluoric acid.—On the formation in nature of vanadium minerals: A. **Ditte.**—On the use of stereoscopical images in the construction of topographical plans: A. **Laussedat.**—The effects of small oscillations of external conditions on a dependent system of two variables: P. **Duhem.**—On a phenomenon analogous to phosphorescence produced by the n-rays: E. **Bichat.** A copper plate is exposed to the action of a bundle of n-rays of definite wave-length, obtained from a Nernst lamp after refraction through an aluminium prism. The secondary rays emitted by the plate are analysed by means of a slit and an aluminium prism, making use of a phosphorescent screen. It is found that, in accordance with Stokes's law, the secondary radiations are of greater wave-length than the primary radiations from which they are derived.—Magnetic observations at Tananarive: P. **Colin.** Tables of the absolute values of declination and inclination for the year ending April, 1904.—The synthesis of a series of tertiary alcohols, starting from cyclohexanol: Paul **Sabatier** and Alph. **Mailhe.** It has been recently shown that cyclohexanol can be readily obtained in quantity from phenol by the action of hydrogen and reduced nickel. By treating with alkyl-magnesium compounds, this substance yields a series of tertiary alcohols. The mode of preparation and the physical properties of a number of these alcohols are given, the reaction appearing to proceed equally well with both fatty and aromatic compounds.—The hydrographic study of the coasts of France, from 1902 to 1903: M. **Laporte.**—On the foundations of a systematic theory of spherical functions: Niels **Nielson.**—On the universal joint: L. **Lecornu.**—On the simultaneous emission of the n- and n_1-rays: Jean **Becquerel.** From the variation in the intensity of a feebly phosphorescent screen under the influence of the n-rays with the angle at which the screen is viewed, the conclusion is drawn that under the influence of the n-rays such a screen emits n-rays normally and n_1-rays tangentially. Experiments in support of this view are given.—The action of anæsthetics on the sources of the n_1-rays: Julien **Meyer.** Sources of n_1-rays, like those of the n-rays, are affected by anæsthetics.—On a new method of obtaining photographs in colours: Auguste and Louis **Lumière.** The method described in the present communication is based on the use of coloured particles arranged in a layer on a glass plate; this is covered with a suitable varnish, and finally with a layer of sensitive emulsion. The plate thus prepared is exposed through the back, developed, and the image thus prepared inverted, giving the colours of the original photograph on looking through it.—On a new regulator allowing of the control of the vacuum in a Crookes's tube: M. **Krouchkoll.** A side tube is blown on to the bulb containing some glass wool. After the tube has become hard through use, it is only necessary to warm the glass wool slightly, when sufficient air is given off to restore the tube to its original condition.—Acetylenic aldehydes. New method of preparation; the action of hydroxylamine: Ch. **Moureu** and R. **Delange.** The acetylene hydrocarbon is heated for twenty-

four hours with an alkyl-magnesium compound. Yields of acetal amounting to about 75 per cent. of the theoretical are obtained. These acetals are readily hydrolysed to the corresponding aldehydes by dilute sulphuric acid. These aldehydes, on treatment with hydroxylamine, do not give oximes, but isoxazols, several of which are described.—The differences of histological structure and secretion between the anterior and posterior kidney in male elasmobranchs: I. **Borcea.**—On the respective functions of the two parts of the adductor muscles in the lamellibranchs: F. **Marceau.**—On the adaptation of the plant to the intensity of light: M. **Wiesner.**—On the permeability of the tegument of certain dried seeds to the atmosphere: Paul **Becquerel.** If the tegument is carefully dried, it is absolutely impermeable to the gases of the atmosphere. In the presence of moisture, however, these gases pass through. Hence the complete suspension of all the phenomena of respiration of the seed is only realised in the absence of moisture.—On the spontaneous radiations of *Sterigmatocystis versicolor*: Paul **Vuillemin.**—A case of the emission of the *n*-rays after death: Augustin **Charpentier.**—The lipolytic property of the cytoplasma of the castor-oil seed is not due to a soluble ferment: Maurice **Nicloux.**—On an albumen extracted from the eggs of the frog: J. **Galimard.**—On the condition of the starch in stale bread: E. **Roux.**—The motive action of the pneumogastric nerve on the biliary vesicle: D. **Courtade** and J. F. **Guyon.**—On the toxicity of the chlorhydrate of amylene: L. **Launoy** and F. **Billon.**—Contribution to the study of Bence-Jones albumosuria: G. **Patein** and Ch. **Michel.**—The amount of albuminoid material necessary in human diet: H. **Labbé** and M. **Morchoisne.**—On ten cases of arterial hypertension treated by d'Arsonvalisation: A. **Moutier.** In all the cases the arterial pressure was reduced to the normal. At the same time, in some of the cases, the symptoms of arterio-sclerosis disappeared in great part.

DIARY OF SOCIETIES.

THURSDAY, JUNE 9.

ROYAL SOCIETY, at 4.30.—Notes on the Statolith Theory of Geotropism. (1) Experiments on the Effects of Centrifugal Force. (2) The Behaviour of Tertiary Roots: F. Darwin, For.Sec.R.S., and Miss D. F. M. Pertz.—The Fossil Flora of the Culm Measures of North-West Devon, and the Palæobotanical Evidence with Regard to the Age of the Beds: E. A. Newell Arber.—On the Structure and Affinities of Palæodiscus and Agelacrinus: W. K. Spencer.—On the Ossiferous Cave-Deposits of Cyprus, with Descriptions of the Remains of *Elephas cypriotes*: Miss D. M. A Bate.—On the Physical Relation of Chloroform to Blood: Dr. A. D. Waller, F.R.S.—Contributions to the Study of the Action of Sea-Snake Venoms: Sir Thomas R. Fraser, F.R.S., and Major R. H. Elliot, I.M.S.—On the Action of the Venom of *Bungarus coeruleus* (the Common Krait): Major R. H. Elliot, I.M.S., W. C. Sillar, and G. S. Carmichael.—On the Combining Properties of Serum-Complements and on Complementoids: Prof. R. Muir and C. H. Browning.

MATHEMATICAL SOCIETY, at 5.30.—The Application of Poisson's Formula to Discontinuous Disturbances: Lord Rayleigh.—Some Expansions for the Periods of the Jacobian Elliptic Functions: H. Bateman.—Types of Covariants of any Degree in the Coefficients of Each of Any Number of Binary Quantics: P. W. Wood.

INSTITUTION OF ELECTRICAL ENGINEERS, at 5.—Annual General Meeting.

FARADAY SOCIETY, at 8.—The Hard and Soft States in Metals: G. T. Beilby.—The Electric Furnace; its Origin, Transformations, and Applications: Adolphe Minet.

FRIDAY, JUNE 10.

ROYAL ASTRONOMICAL SOCIETY, at 5.—The Rotation Period of Saturn: W. F. Denning.—Analyses of Errors of Moon's Longitude for Inequalities of Longer Periods; Methods and Results: P. H. Cowell.—Note on the Gyroscopic Collimator of Admiral Fleuriais: M. E. J. Gheury.—Variation in Latitude of the Greater Sun-Spot Disturbances, 1881–1903: Rev. A. L. Cortie.—The Mass of Jupiter, and Corrections to the Elements of the Orbits of the Satellites, from Heliometer Observations made at the Cape, 1901 and 1902: Bryan Cookson.—The Parallactic Inequality—a Reply: P. H. Cowell.—*Promised Papers*: Solar Parallax from Observations of Eros: A. R. Hinks.—Note on the Distribution of Sun-Spots in Heliographic Latitude: E. W. Maunder.—Micrometric Measures of Double Stars made with the 28-in. Refractor in 1903: Royal Observatory, Greenwich.—Sir David Gill will give an Account of the New Clock of the Cape Observatory.

PHYSICAL SOCIETY, at 8.—Projection of the Indicator Diagrams of a Petrol Motor: Prof. Callendar, F.R.S.—A Model Illustrating the Propagation of a Periodic Electric Current in a Telephone Cable, and the Simple Theory of its Operation: Prof. Fleming, F.R.S.—Exhibition of a Gyroscopic Collimator: M. E. J. Gheury.

MALACOLOGICAL SOCIETY, at 8.—On *Damayantia smithi*, Godwin-Austen and Collinge: Lt.-Col. H. H. Godwin-Austen.—Descriptions of Twenty-nine Species of Gastropoda from the Persian Gulf, Gulf of Oman, and Arabian Sea, dredged by Mr. F. W. Townsend, 1903–4: J. Cosmo Melvill.—*Conus Coromandelicus*, Sin, its Probable Affinities and Systematic place in the family Conidæ: J. Cosmo Melvill.—Descriptions of New Marine Shells from the Collection of the late Admiral Keppel: G. B. Sowerby.—Note on *Voluta brazieri*, Cox: E. A. Smith, I.S.O.—On *Doris planata* of Alder and Hancock: Sir C. Eliot, K.C.M.G.—Description of a Helicoid Land Shell from Central Australia: J. H. Ponsonby.—On Some Semi-fossil Land Shells found in the Hamakua District, Hawaii: C. F. Ancey.

MONDAY, JUNE 13.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—Western Uganda: Rev. A. B. Fisher.

TUESDAY, JUNE 14.

ROYAL PHOTOGRAPHIC SOCIETY, at 8.—A New Principle in Photographic Lens Construction: Conrad Beck.

WEDNESDAY, JUNE 15.

ROYAL MICROSCOPICAL SOCIETY, at 8.—A Direct Proof of Abbe's Theorems on the Microscopic Resolution of Gratings: Prof. J. D. Everett, F.R.S.—Report on the Recent Foraminifera of the Malay Archipelago, Part xvi: F. W. Millett.—Lecture on Nature's Protection of Insect Life, with Lantern Illustrations: F. Enock.

ROYAL METEOROLOGICAL SOCIETY, at 4.30.—Effects of a Lightning Stroke at Earl's Fee, Bowers Gifford, Essex, April 13, 1904: Rev. C. F. Box.—An Instrument for Determining the True Direction and Velocity of the Wind at Sea: A. Lawrence Rotch.

CHEMICAL SOCIETY, at 5.30.—(1) The Mechanical Analysis of Soils, and the Composition of the Fractions resulting Therefrom; (2) The Effect of the Long-continued Use of Sodium Nitrate on the Constitution of the Soil: A. D. Hall.—(1) The Decomposition of Oxalates by Heat. (2) Some Alkyl Derivatives of Sulphur, Selenium, and Tellurium: A. Scott.—The Ultra-violet Absorption Spectra of certain Enol-keto-tautomerides. Part I.: Acetylacetone and Ethyl Acetoacetate: E. C. C. Baly and C. H. Desch.—The Action of Acetyl Chloride on the Sodium Salt of Diacetylacetone and the Constitution of Pyrone Compounds: J. N. Collie.—Our Present Knowledge of the Chemistry of Indigo: W. P. Bloxam.

THURSDAY, JUNE 16.

ROYAL SOCIETY, at 4.30.—*Probable Papers*: The Decomposition of Ammonia by Heat: Dr. E. P. Perman and G. A. S. Atkinson.—On Flame Spectra: C. de Watteville.—On the Origin and Growth of Ripple-Marks: Mrs. H. Ayrton.—The Influence of Rainy Winds on Phthisis: Dr. W. Gordon.

LINNEAN SOCIETY, at 8.—Variations in the Arrangement of Hair in the Horse: Dr. Walter Kidd.—An Account of the Jamaican Species of Lepanthes: W. Fawcett and Dr. A. B. Rendle.—On the Blaze-currents of Vegetable Tissues: Dr. A. D. Waller, F.R.S.—British Freshwater Rhizopoda: James Cash.—Notes on the "Sudd" Formation of the Upper Nile: A. F. Brown.—The Place of Linnæus in the History of Botany: P. Olsson-Seffon.

CONTENTS.

THURSDAY, JUNE 16, 1904.

OXFORD ON THE UP GRADE.

"You will not find your highest capacity in statesmanship, nor in practical science, nor in art, nor in any other field where that capacity is most urgently needed for the right service of life, unless there is a general and vehement spirit of search in the air."

An Oxford Correspondence of 1903. Edited by W. Warde Fowler. (Oxford: B. H. Blackwell; London: Simpkin, Marshall, Hamilton, Kent and Co., Ltd.)

OUTSIDE Oxford, the sub-rector of Lincoln College is known as a nature student—his many "Tales of the Birds" having afforded infinite pleasure to a large circle of readers, old and young, on account of their subject-matter, their truthfulness and sincerity and their great literary charm; within the university, he ranks as an authority on classical subjects. To know the views of such a man, at such a time as the present, is a matter of no slight consequence.

The booklet which Mr. Warde Fowler has most opportunely published takes the form of a series of letters exchanged between a tutor, a certain Mr. Slade, and his pupil, Jim Holmes—who, having distinguished himself by taking a second in Greats and muffed the I.C.S., goes to Switzerland on a holiday; he there falls in with two Swiss professors engaged in bug-hunting and subsequently takes a short course in architecture at Zürich under one of them. Jim is somewhat old for his age—so is Mr. Slade, for an Oxford Don, in the sense that he is far ahead of his time in the liberality of his views: but this no doubt comes of mixing with the birds. When a small boy at a private school, he tells Jim, he was what would now perhaps be called slack; he did not even play games—*but*, he read all the books he could lay hands on collected butterflies and laid the foundation of one other pursuit which had been a constant delight to him all his life since. What this was we may easily guess. He is thankful that he was a small boy then and not now. After referring to the success of several of his schoolmates, he adds:—

"I do not think we could have wasted our time altogether. Anyhow I think we went to our respective public schools with our minds fresh and our interests pretty numerous and lively. If we really were idle boys, then I think that the extirpation of the idle boy, a process on which the headmasters seem to have set their hearts, is a process that needs a little consideration and criticism."

The wisdom of this utterance is beyond question; it is undoubtedly all-important that interests should be developed in early youth and it is unfortunate that the combination of classic with naturalist is so far from being a common one; contact with nature is perhaps the most effective of all means of correcting the narrowness of outlook, the lack of alertness and of observational power, as well as the intolerable self-complacency, which, if not peculiarly characteristic, are far too often met with in the student trained on purely classical lines. Nature can be approached from so many sides, some acquaintance with scientific method can be so easily gained, that the almost complete neglect of natural knowledge by humanists, especially by the Oxford school, is nothing short of inexcusable The irrational conservatism which makes progress so difficult at the present time is probably almost wholly attributable to this neglect.

The story is opened by a letter (full of significant remarks) from Mr. Slade to Jim's father:—

"I fear Jim himself will be disappointed. . . . No one else will mind. Why it is I hardly know but it is the fact that the Greats list attracts much less general attention now than it used to . . . it may be that we don't believe any longer that a man who has taken a first is something quite out of the common. . . . I want him to get into the I.C.S. . . . but honestly I don't think he will. There's a fine quality in him which is apt to be trampled out by these elephantine examinations. . . . He would be a first-rate man for India but I doubt if they will catch him by an examination. Never mind, he will do good work in life as soon as he recovers from the effects of his education."

The kind of consolation administered to the father in this closing sentence is noteworthy. The correspondence shows how the recovery takes place—partly at Mr. Slade's hands, partly because Jim is for a time translated into an atmosphere which should but does not yet exist at Oxford.

Jim's father displays no little sanity of mind in his reply to the tutor's letter:—

"What on earth is to become of Jim if he fails—I should have thought that four years of Oxford with a little finishing at Wren's . . . would make a lad quite safe who had been in the Sixth at a public school and got a scholarship and first in Mods. However, I shall get over it and so must he; he must look out for a mastership or take to architecture like his uncle, who might take him into his office if he meant business. But that is just what Oxford men don't. The young fellows peddle along until the awful question comes down on them and then if you ask what they would like to do they say, they don't exactly know. Affairs of tremendous importance have occupied their attention—boat-races, football matches, tennis and all the rest of it—and after all it is as much our fault as yours; we like to see them enjoying themselves when they come home. And their sisters arrange an out-of-door life for them lasting pretty well all the vacation."

Jim goes to the Maderanerthal with a friend, who is soon called away, however, so that he is left with "only some stupid foreigners, professors, I fancy"; having injured his knee on the way, he is laid up there for a time. Mr. Slade sends him a parcel of books to supplement the novels in the hotel saloon—a translation of Goethe's conversations with Eckermann, Mat. Arnold's "Essays in Criticism," Gardner's "Oxford at the Cross Roads," Bury's inaugural lecture at Cambridge and Boissier's "Promenades Archæologiques." At the same time, he suggests to Jim, "Might it possibly be worth while to cultivate the acquaintance of the stupid professors?" Jim takes the fly gradually but greedily—both books and professors. The bug-hunter exhibits his catch and asks him if he knows Prof. Bolton at Oxford; of course he does not—the prophet having little honour in his own country, especially in the eyes of undergraduates, who have no love for prophets at our universities. But on

writing to his tutor, Jim asks—"Who the mischief is Prof. Bolton?"

The butterfly man, Herr Nägeli, turns out to be a doctor and, after inspecting the knee, actually goes away to fetch bandages, &c., thereby winning Jim's heart; his companion is the architect. The three soon become the best of friends.

Mr. Slade explains in due course who Prof. Bolton is—paying him the well deserved compliment of describing him as "one of the centres of gravity of the world's entomology." In this letter, he refers to Prof. Gardner as

"The Chamberlain of Oxford, who does not see why things should always go on exactly as they have done for fifty years or so and who clearly and resolutely puts out his opinion that there is room for improvement and that we must become less of a big school and more of a real University."

He asks Jim for his opinion of Gardner's book, as that of a "friendly person not wholly without intelligence" who has lately been himself through the mill which, according to Gardner, "is very much out of order and needs new scientific appliances to make it grind well." The opinion comes a good deal later: that it may be well to keep the essential principle of Greats but to adjust it to new needs, finding a way somehow to give a man a chance of keeping his kettle really on the boil.

Jim develops apace in the free Swiss air under professorial guidance. In acknowledging the arrival of the books, he confesses that he has not yet recovered the taste for reading. "I feel," he says, "with a friend devoted to natural history who complained that he had not time to read, '*for as long as there is light I want to be looking at things.*' Books may be made for men, but I deny that man was made for books."

In the next letter or two, the subject discussed is the need of treating every subject from a scientific point of view, Mr. Slade remarking:—

"It is astonishing what nonsense able men will sometimes write, just because they don't know even the elementary laws of scientific investigation." And he then dwells on the importance of attention to style in writing—of attention "to the 'ars rhetorica,' which is after all in its proper sense only the result of a conscientious effort to think clearly and get down your meaning neatly. Rhetoric need not mean adornment, though it is often used in that sense. No one would call Darwin a rhetorican, yet he was one in so far as he positively refused to let any sentence stand of which the meaning was not clear in his mind and pellucid to the reader."

Matthew Arnold is referred to on the same subject. The letter ends in a P.S., in which the following most appropriate passage from Roger Ascham's "Scholemaster" is quoted:—

"All soch Authors, as be fullest of good matter and right judgement in doctrine, be likewise always most proper in wordes, most apte in sentence, *most plain and pure in uttering the same.*"

"If I am not mistaken," Mr. Slade adds, "this would have delighted Darwin." His appreciation of Darwin is indeed very noticeable; it is much to be desired that the example which Darwin has set—his modesty, his reverence of fact and of exactness—should be brought home to humanists generally. Jim hits the nail on the head in a subsequent reply in saying:—

"I never had enough to say to trouble much about how I said it; I think that's probably the mischief rather than rhetoric—want of stuff and the necessity of writing an essay when you know nothing about the subject and care less, &c."

We seldom realise how often "want of stuff" is at the root of schoolboy failures. The discussion may be commended to the many schoolmasters who, thinking to teach English composition,[1] vainly require their pupils to write essays on subjects of which they know practically nothing and in which they cannot take the slightest interest. It is worth noting that Prof. Gardner takes up a similar attitude in his "Oxford at the Cross Roads":—

"If men were set to write out clearly what they had really learned, it would be an excellent training. But I think that to set men to write on subjects about which they know little and about which under the conditions they can learn but little is not merely inexpedient but radically immoral. It trains the writer to conceal his ignorance, to pretend to know what he does not know, to cultivate sophistries of all kinds. And worst of all, a man who has once learned the fatal art of writing plausibly, without knowledge, will scarcely in after life be persuaded to take the pains necessary in order to discover the truth of things."

We next come to a very important *dissertatio de examinationibus*. After the I.C.S. exam. Jim writes:—

"My mental liver is out of order as well as my bodily one. They do their work well at Wren's and we slaved away in the heat all day like convicts; the unlucky lecturers seem to bemoan their fate and would fain go into things a little further than they dare, but they are slaves of the lamp too—the glorious illuminating lamp of competitive exam."

In writing of his failure to pass the exam. he gives utterance to a truth which we too often lose sight of in considering examinations:—

"These . . . (adjective to taste) competitive examinations do as much harm as good by damaging more than half the competitors for no reason at all."

In his reply, Mr. Slade proceeds to "uncork himself" in a very noteworthy manner: —

"Exams there must be of one kind or another; but the less we have of exams that do not positively help us in education the better we shall be as a nation. . . . We in England have become so completely salted, soused and pickled in these exams, that we no longer use our natural intelligence in judging of them. We take them for granted and never or rarely inquire into their effect on the human mind. We have lost the power of summing up the general result of them on the nation during a long series of decades. . . . I am strongly inclined to think that our system of exams has seriously damaged the natural intelligence of the nation by almost destroying the freshness of interest which a fair average of boys ought to take in their work and by robbing them of much

[1] It is quite likely that we may progress apace. I notice in the May number of the *School World* an interesting article on the teaching of English by a master at Haileybury College—who actually urges that English boys should be taught English by much reading of English books and by speaking; who can say there is no hope for the future when such things are happening?

mental freedom and elasticity. We get into a habit of looking at knowledge in terms of examination. . . ."

The really important subject in the essay—for Oxford—is first touched upon in a P.S. by Jim, who says:—

"I have been looking into the 'Crossways' again. What does he mean when he says that everyone ought to do a piece of first-hand work? A piece of work that no one has done before? I am so ignorant that this puzzles me. Have you ever done such a thing?"

The sweet innocency of the young English graduate is well displayed in this passage. Mr. Slade is clearly cornered; he answers:—

"Excuse my saying that you are an 'enfant terrible.' You ask me if I have ever done a piece of first-hand work? . . . I decline altogether to answer the question. But I will tell you that the joy of discovering something that you did not know before is in my experience very great, and that the joy of finding that so far as your knowledge goes no one ever found it out before is far greater. I have not ever dug up anything, or caught any insect, as yet unknown to the world: but I do know how the world feels to you when you have found a new clue to an old mystery. But what Gardner meant, I think, is this: that every real student who means to occupy himself with subjects proper to a University in these days should not delay too long to try his hand at a piece of original work, suggested perhaps by a Professor or someone of real learning and certainly supervised by him: so that he may not waste time in doing what other people have done before, or in going to work the wrong way for want of knowledge of the right way to set about it. . . . The wares of German workers have become part of our stock-in-trade in Oxford and we retail them often without even marking them as 'made in Germany.' You take them all from us without questioning, without testing them, and when the examination is over you let them moulder away in obsolete note-books and sell such few books as you do possess to second-hand booksellers. Why could not *we*, too, do something in the way of investigation? No doubt some of us do, but we do it under great disadvantages, because we have no pupils who help us, or want supervision in such work themselves, and so keep us at the boiling-point. We are so many kettles that never quite get to the boiling point. . . . Yes, the tea that we make is generally weak—made with water out of kettles that have never got beyond a gentle singing on the hob. Now do you understand what Gardner wants? I daresay he is thinking of his own Archæology, in which original work and good training are essential, and more obviously so perhaps than in some classical departments: but you may take my word for it that in every department of learning the same thing holds good and that a University that does not find some room for original work, but insists upon foreign supplies, is pretty sure to lose its reputation sooner or later."

Jim settles down to work at Zürich; but somehow it doesn't seem like work: he finds that a student there *is* a student, not a gamester; and is led to believe that the professor of architecture is really keen that he should do something worth doing. His tutor, in replying, expresses his delight at hearing that he is starting work with a sense of its not being work—or at any rate grind; then he enters on a dissertation to explain why work is grind for so many Oxford men:—

"A few men," he says, "of course are 'keen,' but not nearly enough for a great University. Is it the examination system, or the charms of out-door Oxford, or national feebleness, or overwork at school (including games), dullness of lecturers, or over-conscientiousness on the part of tutors, who do so much for their pupils that they extinguish the desire, natural (I should imagine) to human beings, as to cats and dogs, to find out things for themselves? Or is it a disease accompanied by so many symptoms that it is impossible to tell which is the primary one, or where the doctor is to begin operations?"

At the end of two months Jim is sent by his professor to survey the houses in a certain district near to the Austrian frontier, to see if they are really as primitive as they are reported to be. He goes off with knapsack and camera; after a few days he returns with a number of photos, measurements and a report in English: being no longer hampered by "want of stuff" he is able to write. The reception he meets with somewhat startles him: after examining the photos for a minute, the professor embraces him; what happens as he reads the report, modesty forbids Jim to tell—but his description of the interview is none the less graphic:—

"I never yet saw a college tutor go and fetch two bottles of beer while reading a man's essay, to overcome his feelings. The fact is that the poor man does not get pupils who can write, and as I had put down exactly what I saw and what I thought to the best of my ability and in my own tongue, it was something quite new to him. We had to clink glasses so often that I began to be afraid I should be up all night and ill the next morning. . . . Before we parted he uttered these memorable words: 'You are a very remarkable young man.' No, I am not a very remarkable young man, but I have found out that I can take a tremendous interest in a bit of work when it is new and with some relation to my life's work as it is to be. And I think I can put a fair amount of intelligence into it. Is this what Gardner means by first-hand work? If so I am a convert to his views."

There is no need to point the moral of Jim's conversion: we can scarcely doubt what the result would be if professors at Oxford could be got up to the beer point of enthusiasm—many of the graduates might then "find themselves" while at the university, and would receive the most efficient preparation possible for the work of life. It is only necessary to visit, for example, the Hope collections at the museum in company with their curator to see how "a vehement spirit of search" can be developed even by the study of a few butterflies. But the iron grasp of examinations must be relaxed to make progress possible.

It is a significant fact that Mr. Warde Fowler's book should follow so closely that of Prof. Gardner—by which it is obviously inspired. We have to recollect also the correspondence on research at Oxford printed in *The Times* last summer. The "spirit of search" is clearly hovering over the university: we may hope that it will, ere long, descend upon it and dominate every branch of its work. The remarkable passage at the head of this article is printed by Prof. Gardner on the title-page of his "Oxford at the Cross Roads"; it expresses the opinion not of a writer on any branch of experimental science but of a literary authority, Mr. John Morley, being taken from his "Rousseau." It may be said without hesitation to

embody the policy which we should adopt as a national policy, which alone can give us an assured position as a nation, as we are bound to develop a forward policy.

Prof. Gardner's work is essentially a plea for the reconstruction of humanist studies—but he is not altogether free from the narrowness of outlook which is so often met with in the humanist. "If," he says, "the lead in higher education is left to Manchester or to London, the turn which it will take is probably not towards a more enlightened and scientific humanism but towards physical science. The study of nature will encroach and the study of man recede."

Whereas, however, in ancient times, the study of nature held an entirely subordinate place in the scheme of knowledge, we have now to recognise that man is but a part of nature; and since we have tamed the forces of nature to the service of man, an enlightened and scientific study of humanism is impossible without considerable knowledge of physical and biological science; it must, therefore, be the work of the universities to develop the application of scientific method to all branches of study, as humanism will suffer grievously if studied from a too narrow point of view. Matthew Arnold recognised this when he wrote:—

"The ideal of a general liberal training is to carry us to a knowledge of ourselves and the world. . . . The circle of knowledge comprehends both the study of the humanities and the study of nature and we should all have some notion, at any rate, of the whole circle of knowledge."

May the birds and the butterflies help us to sounder views!

Conduct is impaired, he says, by the want of science and culture. That our universities should hold so narrow a conception of culture as to accord a knowledge of scientific method no regular place in the curriculum is a striking commentary on the sufficiency of humanist studies as hitherto conducted.

H. E. A.

A NEW TYPE OF BOTANICAL TEXT-BOOK.

Lehrbuch der Pflanzenkunde für höhere Lehranstalten. By Dr. Karl Smalian. Pp. iii+626; illustrated. (Leipzig: G. Freytag.) Price 8 marks.

IT has become more and more clear of late years that for one man to write a satisfactory text-book of modern botany is practically an impossible task. It is true that such text-books do appear, fortunately at much rarer intervals than formerly, but they only serve to give support to this view. The well known "Bonn text-book," which has run through so many editions, is a step in the right direction, for though the whole is complete in a single volume, the authorship is composite. It cannot be long, however, before the student will finally have to give up the long cherished belief that it is possible to find within the covers of a single volume a complete manual of his subject. Dr. Smalian's volume, with its numerous closely printed pages, suggests an attempt in this direction, but an examination shows that the author has succeeded in producing a text-book of a distinctly novel type.

General and special morphology and physiology are relegated to the last hundred pages, while the whole of the rest of the book deals with the plant from what is usually termed the natural history point of view. A large number of plants, representatives of the chief natural orders, are selected, and an attempt is made to give a picture of them as living beings. Their naked eye anatomy is described, and its relation to their environment, both animal and vegetable as well as inorganic, is considered. Any special adaptations which they may exhibit are dealt with, stress being laid on their exact method of pollination, while their geographical distribution and their uses to man are also included. In many cases, to make the picture more complete, any striking animal or vegetable parasites which may seriously affect the life of the plants under consideration are figured and described. The œcological factor and the question of plant communities are always kept clearly in mind.

The descriptions of the plants are exceedingly well done, and are profusely illustrated with figures in the text, all the more important orders, both European and exotic, being dealt with, some at considerable length. Thus, under Ranunculaceæ, after an account of the external anatomy, habitat and environmental relationship of *Ranunculus acris, Ficaria verna, Caltha palustris* and *Anemone nemorosa*, no less than twelve genera are treated in detail. Furthermore, when occasion arises, other matters of general botanical interest are discussed. The Rosaceæ are an excuse for dealing with various methods of grafting; under Leguminosæ the nature of root tubercles, the morphology and function of tendrils, the movements of sensitive plants are all described. When dealing with the Horse-chestnut, the structure of the buds and their method of opening are made clear with the help of exceedingly good figures. Insectivorous plants, parasites, saprophytes, leaf mosaic, &c., are all dealt with in their appropriate places, and in considering domestic plants, such as the carrot, the striking effect on the plant of change of environment is pointed out, and a short digression made to consider the differences between mutations and variations.

The part dealing with morphology and physiology is by far the smaller portion of the book, and is of too condensed a nature to be of much value. The figures are in the main well chosen, but surely in these days of active cytological investigation of plants it is not necessary to illustrate nuclear division by a series of schematic figures drawn from an *animal* cell.

It is clear from what has been said above that the main portion of the book is literally packed with information, and certainly the author has made good the two claims in his preface, that he has given "einen reichen Stoff," and put it forward in a *readable* form. Of its value to teachers, and as a book of reference, there can be no question, and the author must be congratulated on the pen-pictures of the selected plants. But it cannot be considered satisfactory as a text-book, for its sheer plethora of facts must surely produce mental indigestion even in a subject endowed with such strong assimilating power as

the German student. Also, in a general text-book, a study of the common finer adaptations of the parts of the plant machine to one another and to ordinary conditions of environment, *i.e.* general morphology and physiology, should certainly not be sacrificed to a study of the almost endless variety of special, grosser adaptations by which plants fit themselves to special conditions of life.

The book is certainly a marvellous example of German publishing, for it has 600 pages of good paper, 597 very good figures in the text, 36 fairly satisfactory coloured plates, and the whole is well bound in serviceable and artistic cloth covers; yet the cost is only 8 marks. In no other book can so much valuable botanical information be obtained at so cheap a price.

V. H. B.

A SYSTEM OF GEOGRAPHICAL CLASSIFICATION.

Katalog der Bibliothek der Gesellschaft der Erdkunde zu Berlin. Versuch einer Systematik der geographischen Literatur. Bearbeitet von Dr. Paul Dinse. Pp. xxvii+925. (Berlin: Mittler und Sohn, 1903.) Price 12 marks.

INTENDED primarily as an index to the contents of the library of the Berlin Geographical Society, this catalogue will be of service to a far wider circle than is constituted by the members of that body. While forming probably the best guide that has yet appeared to the literature of geography in general (for few works of real geographical importance will be found to be excluded), it does a second and no less important service in the direction of a classification of geography, a service of especial value in the present stage of the development of the science.

Dr. Dinse, who is himself both a geographer and librarian, has evidently bestowed much thought and pains on the elaboration of the system adopted, and the general result is thoroughly satisfactory. The whole arrangement of the body of the work is a subject one, all the purposes of an authors' catalogue being at the same time supplied by the alphabetical index, which has been kept within small compass by a judicious abbreviation of titles. In the rest of the work the compiler has wisely eliminated the alphabetical arrangement, the fetters of which too often mar the usefulness of attempts at subject classification. Two main divisions are laid down at the outset, the first concerned with the wider and more general aspects of geography, the second with the topographical subdivisions of the earth's surface. A glance at the schedule of classification for the former category shows in a striking way the great development of geographical science within recent years, the subject-matter being divided into no fewer than eleven main divisions, most of them in turn subdivided into groups of the second, third or fourth order. It may possibly be thought that this minute subdivision militates against facility of reference, as few bibliographical items are of so restricted a scope as to belong definitely to one ultimate subdivision only. But this objection has to a certain extent been met by a duplication of entries. Of the eleven main headings, that denoted "general physical geography" is naturally the most comprehensive, while of its eight subdivisions, the last, or "geomorphology," is perhaps the most important as dealing with what may be regarded as the kernel of the whole science. On the whole, the groups are logically and clearly defined, though it is perhaps inevitable that the boundaries should occasionally lack this character of precision. It is not easy, *e.g.*, to draw a hard and fast line between geophysics and geomorphology, for both seismology and vulcanism might, from one point of view, be rather grouped with the former than (as is done by Dr. Dinse) with the latter. Again, the reason for the order adopted is sometimes not quite apparent. Thus historical topography (Länderkunde) seems separated by a needlessly wide interval from the history of geographical science in general. But such difficulties are no doubt inseparable from any attempt at a linear arrangement of mutually inter-related groups. In the topographical section political divisions are necessarily taken as a basis, but others of a more elastic nature, in part based on physical factors, have been wisely introduced alongside of the former.

It should be mentioned that the catalogue deals not with books only, but with the contents of a certain number of series or collections, besides including the titles of a large number of separate copies ("Sonderabdrücke") of articles in geographical periodicals.

E. H.

OUR BOOK SHELF.

The Sporting Dog. By J. A. Graham. American Sportsman's Library. Pp. x+327; illustrated. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1904.) Price 8*s.* 6*d.* net.

QUITE apart from its interest to the class for whom it is primarily intended (and to whose requirements it appears in every way admirably suited), this volume appeals strongly to the naturalist and to the student of variation. Despite certain pretensions (of which the author makes very short work) of some of them to derivation from "native breeds," American sporting dogs, other than mongrels, are admittedly derived from English stocks, but their new environment, and the different conditions under which they are employed, have in all cases, except that of the greyhound, caused them to display considerable variation from the parent type. It is the author's description of these variations which will cause his volume to have a considerable interest and value to the naturalist.

"It is foxhounds and shooting dogs," writes Mr. Graham in his introductory chapter, "which have become, under American conditions, something essentially different from what the British sportsmen established and have maintained as filling their conceptions of utility and good looks. Reduced to the simplest terms, the change wrought over here comes to this: the dry climate of extreme temperatures, the nature of the ground and game, and the methods of hunting the fox and shooting game birds cause the survival of the fittest to proceed in the direction of a faster, lighter, more enduring animal; perhaps not more sensitive of nose, but quicker in the reflexes of judgment and action which are the sequences of scent."

In a word, pace and the capacity to act on his own initiative, rather than as a member of a pack, are the

essential features of an American foxhound, while among pointers (which are special favourites in America) and setters a greater proportion of energy to weight is the feature at which the breeder aims. The admirable reproductions from photographs with which the excellent little volume is illustrated fully bear out the author's statement as to the marked physical differences of the dogs he describes from their European prototypes. R. L.

Histoire de l'Habillement et de Parure. Bibliothèque scientifique internationale. By Louis Bourdeau. Pp. 302. (Paris: Félix Alcan, 1904.) Price 6 francs.

THE history of clothing and of ornaments is an important aspect of the history of culture, and it well deserves independent treatment. M. Bourdeau deals with the primitive articles of clothing, skins, natural vegetable products and the like, the method of working these, and the fabrication of textiles and the methods of colouring them. The making and wearing of clothes are briefly noted with the history of costumes, in which are included dressing the hair, head, hand and foot gear, umbrellas and jewellery. The scheme is good enough, but, as the work is confined to 299 pages, the treatment is necessarily slight, for the author begins with Genesis, quotes Greek and Roman authors, and, glancing at intermediate periods, finishes with modern industrialism, making allusions by the way to non-European peoples of varied culture.

The book can be recommended to those who require a light, popular sketch of the history of clothing—the serious student will, however, be disappointed. The author's knowledge of ethnology appears to be extremely limited, judging from the imperfect statements in, and the omissions from the book; for example, the paper mulberry tree is not mentioned; he is unaware of the practice of the Roman Catholic women of Bosnia and Herzegovina to tattoo themselves so as to be further discriminated from the followers of Islam; like most other writers, he does not distinguish between the Maori *moko* and ordinary tattooing. No mention is made of the production of patterns in cotton fabrics by tightly tying several strands of a warp in different places and then dyeing the whole, which technique is carried to a high degree of excellence by many Malayan peoples; nor is the analogous method of waxing fabrics and dyeing the unwaxed portions referred to. Melanesians are confounded with Polynesians (p. 229), an error as great as speaking of Negroes as Europeans. But it is in the section on ornaments that the author is weakest. It is now well recognised that what are generally spoken of as "ornaments" are worn by nature-folk and by barbarians for magical purposes as prophylactics to ward off evil, to ensure good luck generally, or to produce some definite result. This aspect is entirely ignored by M. Bourdeau. Many "ornaments" have the value of currency, but probably very few are worn solely for purposes of adornment. There are no illustrations, and, as is usual with this class of book, there is no index.

The Ether: Some Notes on its Place in Nature. By John Rhind. Pp. viii+87. (Wick: W. Roe, 1904.)

LIKE the mythical Dog Diamond, Mr. Rhind little knows what mischief he is doing. If his amendments of accepted beliefs were adopted, the well built doctrine of science would become no better than

"a tale told by an idiot,
"Full of sound and fury, signifying nothing."

Mr. Rhind's knowledge of principles goes no deeper, apparently, than the most popular utterances of popular lecturers and writers, and these are subject to amendment *ad libitum* to square with "common sense." With this slender equipment he does not falter to lay violent hands upon the theory of gravitation, the conservation of matter, and the nebular hypothesis.

A single example (p. 45) of the method will suffice:—"We would suggest that the earth may have the power of converting, or in other words of condensing, the ether into oxygen, which is the principal agent in sustaining life. The sun's atmosphere being so much more powerful, will be able to condense this element into an electric fluid which, being sent to his planets, gives them light and heat, and in combination with the oxygen of our earth and its atmosphere completes the power, if not of introducing life, of maintaining the life that already exists on our globe." It seems that (p. 48) "ether, oxygen and the electric fluid are only different manifestations of the same substance." The moral of the book appears to be that if science were adequately taught us at school, a gentleman with an active and spontaneous interest in natural phenomena need not in after life go so pitifully astray.

A Safe Course in Experimental Chemistry. By W. T. Boone. University Tutorial Series. Pp. vi+180. (London: W. B. Clive, 1904.) Price 2*s.*

THIS little volume is quite up to the standard of the best of modern elementary books on practical chemistry. It clearly embodies the experience of a thoughtful teacher who has made his students work and think accurately, and is not without originality of treatment in the arrangement and character of the exercises.

It has the fault of all experimental books which ignore the presence of the teacher, inasmuch as it is forced to supply wordy and involved descriptions of such simple operations as, for example, removing a stopper when using a stoppered bottle, which a demonstration would make clear in a moment.

One of the "rules for a chemical laboratory" laid down at the beginning of the book—"do not use more of a reagent than is necessary"—raises an obvious question which might be difficult to answer at this early stage, and is rather like telling a child not to eat too much.

The use of the word "safe" in the title conveys a flavour of quackery, which is a little unfortunate in a book of much solid merit. The illustrations serve their purpose, no doubt, but the handiwork of the amateur is a little too evident.

Apart from these few criticisms, the book, as already stated, deserves a good reception. J. B. C.

Catalogue of British Coleoptera. By T. Hudson Beare, B.Sc., and H. St. J. K. Donisthorpe, F.Z.S. Pp. 51. (London: Janson, 1904.)

THIS is one of the lists which are imperatively required by students of British entomology to keep them informed from time to time as to what species are actually considered by good authorities to be found in these islands, genuine additions being allowed for, and doubtful records eliminated. The print is clear and good, and another edition on stout paper, and printed on one side only, to be used for labels or notes, has been issued. The authors' names are a sufficient guarantee for the care and accuracy with which they have apparently done their work. The list contains 3274 species admitted as indigenous, and there are supplementary lists of introduced or doubtful species. The introduced list is headed by two very conspicuous species, which, though not unfrequently taken in England, can hardly be considered indigenous. These are *Carabus auratus* (often introduced with vegetables, &c.) and *Calosoma sycophanta.*

The last critical list of British beetles, by Sharp and Fowler, was published eleven years ago, and we heartily recommend the present list to British entomologists.

A Preliminary Course of Practical Physics. By C. E. Ashford, M.A. Pp. 48. (London: Edward Arnold, 1904.) Price 1s. 6d.

THIS little book on practical physics is of a kind familiar to teachers of the subject. The experiments are simple and well within the power of schoolboys, but so far as we have examined them they differ little from those to be found in well known books. Indeed, in his preface the author says it is impossible adequately to acknowledge the debt "to those from whose books many of the experiments have been derived." But though the book contains much in common with previously published first courses of practical physics, the author has compiled a logical and useful manual of experiments which will serve to introduce boys to the study of physical science. The volume may be recommended to the attention of teachers deciding upon a book to place in the hands of their pupils.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

On the Radio-activity of Natural Gas.

IN a paper by Mr. E. F. Burton, recently published in the *University of Toronto Studies, Physical Science Series*, an account is given of some experiments with a highly radio-active gas obtained from crude petroleum. In this investigation it was found that air drawn through crude petroleum became charged with a radio-active emanation which, from the rate at which its activity decayed and from the nature of the induced radio-activity which it produced, the author concluded to be an emanation from radium.

The present writer has extended this investigation to an examination of the natural gas from different wells in western Ontario. The gas from every well examined, which included those in the Welland district, in the neighbourhood of Niagara Falls, as well as those near the city of Brantford, was found to be charged with a radio-active emanation. The activity of this emanation in all the gases tested was found to decay or die out to one-half its original intensity in about three days, and the intensity of the induced radio-activity which it produced died down to one-half value in about forty minutes.

The wells examined varied in their depths, but the amount of active emanation present was found to be practically the same in all wells coming from the same horizon. In the Welland district, the gas from those wells which had their source in the stratum known as the Niagara formation, and which were about 500 feet deep, possessed the highest initial conductivity. On an arbitrary scale this conductivity is represented by about 2000.

The gas of those wells which had their source in the Clinton limestone, 750 feet deep, possessed an initial conductivity of about 300 on the same scale, while that from wells coming from the Medina formation, about 900 feet deep, gave an initial conductivity of about 1200. One well, which had its source in the Trenton limestone, and had a depth of about 3000 feet, possessed an initial conductivity of about 200. The highest conductivity obtained in the investigation was that of the gas from a well near the city of Brantford, the conductivity in this case being about 9000. An investigation of this gas showed that, under the action of the emanation with which it was charged, there was produced, at normal pressure, about 15,000 ions per second in each cubic centimetre of its mass.

A test made on the conductivity of ordinary air, confined at atmospheric pressure in the receiver used in making the measurements on the conductivity of the different samples of natural gas, showed a production of 32 ions per cubic centimetre per second. J. C. MCLENNAN.

University of Toronto, May 28.

The Source of Radio-active Energy.

IN NATURE of June 2, Mr. Jeans brings forward the view that the energy manifested in radio-active processes is derived from the coalescence of positive and negative ions, thus involving an annihilation of matter. For some time it has seemed to me that some such fundamental change is needed to account for the observed phenomena, and I therefore venture to submit some general and numerical considerations bearing on this view.

Mr. Jeans is inclined (as I understand) to attribute the beginnings of the process to a change of type in advancing æthereal waves, arising from a lack of strict linearity in the equations of the electromagnetic field. It may be pointed out, however, that whether or not the circumstances of æthereal wave-propagation are strictly expressible by linear equations, there is a *universal tendency* towards loss of kinetic energy in orbitally moving systems of electrons. Unless the orbital periods are very long compared with the time taken by radiation to traverse the assemblage, there must be appreciable radiation of energy, and it is thus a necessary condition of permanence or quasi-permanence that *the orbital velocities should be very small compared with the velocity of light.* This view is confirmed by numerical consideration of simple cases in which the orbits are assumed to be of *atomic* dimensions; it is also borne out by the general optical properties of matter.

It should be remarked that as energy is dissipated and orbits become contracted, with corresponding rise of velocities, the total effective radiation will become more and more intense, so that conceivably very little time may be occupied in the transition from a quasi-permanent motion to a state of collapse and disintegration; indeed, once the orbital motions have begun to give out perceptible radiation, the life of the system must be excessively short.

Thus, whether we look for the main source of radio-active energy in enormous orbital velocities due to intra-atomic rearrangement, or in the constitutive electrostatic energy of individual electrons set free by mutual annihilations, the conditions favourable to radio-activity in any given atom must be confined to a momentary phase—momentary, that is, as measured by ordinary standards. It is not a long step from this conclusion to an exponential law of decay of radio-active matter.

If we adopt provisionally Dr. H. A. Wilson's very interesting suggestion (NATURE, June 2) that, the positive and negative electrons having numerically equal charges, the greater mass of the positive electron is due to its smaller diameter, it follows that *any* isolated electron has electrostatic energy $=\frac{1}{2}m.3V^2$, where m is the mass of the electron (when moving slowly) and V is the velocity of light. In other words, when matter of mass M is annihilated, energy $=\frac{1}{2}M.3V^2$ is set free—initially as an electromagnetic pulse of great intensity. *A further assumption involved in this estimate is the validity of the ordinary electrostatic-field relations for such enormous intensities as obtain in the neighbourhood of an electron.*

If annihilation of matter furnishes the energy of radio-activity, it follows from our estimate that, in the case of radium, the coalescence of one pair of electrons causes the break-up of a large number of radium atoms (something of the order of one hundred), otherwise the total energy emitted by radium would be much greater than that which has been observed by Curie and Laborde.

If the assumption in italics above is very wide of the mark (which is conceivable), our estimate of the energy of annihilation is probably in excess.

It may be supposed that some neighbouring atoms, which are not actually broken up by the pulse arising from a pair of coalescing electrons, receive a sufficient access of kinetic energy to *prolong* their existence. "Metabolons" of short average life may be conceived of as consisting of assemblages the orbital motions of which are especially liable to be damped out rapidly by radiation of energy.

Cambridge, June 9. C. V. BURTON.

NEW LAND.[1]

On June 24, 1898, a vessel, insignificant in size and somewhat quaint in appearance, unlike ships generally engaged in ordinary mercantile avocations, might have been seen threading her way, under her own steam, through the numerous merchant ships that were at anchor in the harbour of Christiania. She was a vessel of no common type; her peculiarities of construction and rig were noticeable, even to the inexperienced eye of a landsman, and judging from the enthusiastic cheers with which she was greeted on all sides, she was evidently bound on a voyage of no common interest. The ships in harbour were all decorated with gay bunting; flags flew from their mastheads, and cheer after cheer resounded from their crowded decks and rigging as she steamed slowly past. The quays and wharves along the shore were also thronged with a vast concourse of people, bedecked in their smartest and gayest holiday attire, all equally enthusiastic in their demonstrations of farewell, while the fjord itself was alive with innumerable boats of all descriptions, including many small steamers, all intent upon one object, namely, to do honour to the little vessel that was so quietly proceeding to sea, and to wave her a last good-bye.

What was the cause of all this enthusiasm and excitement? and why was this little craft the centre of so much attention and attraction?

A glance at the name on her stern revealed the fact that she was the *Fram*, and that she was bound on an important voyage of geographical exploration and scientific research in high northern latitudes.

She was the same little *Fram* that was specially designed and constructed for Dr. Nansen in 1892, and had carried that bold explorer northwards on his memorable and adventurous voyage towards the North Pole. His second in command, and navigating officer, on that occasion was Otto Sverdrup, an officer of the Norwegian mercantile marine, who had been specially selected for the appointment in consequence of the experience he had gained in ice navigation while serving as a mate on board a Greenland whaler.

It was the same Otto Sverdrup who was in command of the little *Fram* as she steamed out of Christiania Harbour on the occasion to which we refer, but in this instance he was not only commander of the ship, but was also the leader of the expedition. He had already won his laurels as an Arctic explorer, and had proved himself a careful, as well as a skilful, navigator in ice-encumbered seas. His selection for the command of the *Fram* was more than justified, as a perusal of his account of the voyage, which has recently been published under the title of "New Land," will abundantly testify. The book, originally produced in Norway, has been well and ably translated into English by Ethel Hearn. The narrative of the cruise is presented to us in the shape of two handsomely bound volumes, profusely illustrated from sketches and photographs taken by members of the expedition. It is perhaps unfortunate that a great many of the illustrations in the text are not inserted on the pages to which they refer, but this does not detract from their excellence. The story as related is the plain unvarnished tale of a sailor; the incidents are graphically described, and a vein of humour pervades the whole narrative.

The Introduction informs the reader very curtly as to the origin of the expedition, and how it was that Otto Sverdrup was selected as leader. He writes :—

FIG. 1.—Seventeenth of May, 1899. From "New Land," by Otto Sverdrup.

[1] "New Land. Four Years in the Arctic Regions." By Otto Sverdrup. Translated from the Norwegian by Ethel Harriet Hearn. 2 vols. (London: Longmans, Green and Co., 1904.) Price 36s. net.

"A few days after our return from the first Norwegian Polar Expedition, we were lying in Lysaker Bay unloading the *Fram* when Dr. Nansen came on board. 'Do you still wish to go on another expedition to the North?' he asked me.' 'Yes, certainly,' I answered, 'if only I had the chance.' He then told me that Consul Axel Heiberg,[1] and the firm of brewers Messrs. Ringues Brothers,[1] were willing to equip a new scientific expedition with myself as leader."

The Norwegian Government, realising the value of the work it was proposed to carry out, in a truly patriotic spirit well worthy of emulation, placed the *Fram* at the disposal of the promoters of the enterprise, and generously added the sum of 1100*l.* to assist in defraying the cost of the expedition. The main object was the exploration of the north coast of Greenland by way of Smith Sound and Robeson Channel, in fact, to follow in the footsteps of Nares's expedition

FIG. 2.—Sledging expedition ready to start. Spring, 1901. From "New Land," by Otto Sverdrup.

in 1875; on reaching the highest point attained by our countrymen on the north coast of Greenland, the explorers were to continue along the coast, and as far to the east as it was possible to reach—in other words, to determine by actual exploration the insularity of Greenland.

There was to be no question of trying to reach the North Pole!

In the event of unforeseen difficulties interfering with the successful accomplishment of this project, Captain Sverdrup was at liberty to use his own judgment and discretion in formulating a revised programme that would, in his opinion, be the best to further the interests of geographical exploration and other scientific investigations.

The liveliness of the little *Fram* during the first few days in the Atlantic, when somewhat stormy weather was encountered, is thus jocosely alluded to by the author:—

"The members of the expedition, who were not much used to the sea, turned very white, and looked extremely serious. They trooped to the doctor and complained of various symptoms; some had headache, some shivering fits, and some pains in the stomach, which they had contracted, they knew not how; but none of them mentioned the malady by its right name. The doctor, however, came to the conclusion that the complaint with the many different aspects, had a single and fairly simple name, to wit, sea sickness; and for it there was but one and an equally simple remedy, dry land. Unhappily we had forgotten to bring any with us in our otherwise so well equipped Expedition, but it was hoped it might be found somewhere north in the Arctic Ocean, and this appeared to console the sufferers."

Time, however, as is usual in similar cases, soon restored the ailing ones to their customary health and the free use of their sea-legs! The complement of the little ship was, exclusive of the captain, only fifteen souls. In this small number was included two deck officers, a doctor, cartographer (who, by the way, was a cavalry officer), botanist, geologist, zoologist, two engineers, a steward, and four others who made themselves generally useful in carrying out any duties that might at any time be apportioned to them. All, it is almost unnecessary to add, assisted in the working of the ship when at sea or in the ice.

On reaching Smith Sound, their further progress north was effectively barred by an impenetrable ice pack. After several unsuccessful attempts to push through, they were at length compelled to go into winter quarters, on the west side of Smith Sound, not very far from its entrance, in a small partially

[1] These gentlemen had contributed largely in assisting to defray the expenses of Nansen's expedition!

sheltered bay, which they appropriately named Fram's Haven.

The winter passed pleasantly. They were fortunate in securing abundance of fresh meat in the shape of musk oxen, hares and ptarmigan, while they were also lucky enough to kill several walruses, which afforded them an excellent opportunity of laying in a large stock of food for their dogs, of which they had about seventy on board.

It is a pity that Captain Sverdrup in his narrative should have considered it desirable to alter the nomenclature of that animal which has so long, and so universally, been known as the musk ox. Its scientific name is the *Ovibos moschatus*, and it was so called in consequence of the musky odour which has always been associated with its flesh. Captain Sverdrup, simply because he failed to detect this strong scent in any of the beasts killed in his expedition, somewhat arbitrarily alters the name by which they have hitherto been known to that of "polar ox." This is a misnomer, for although the animals have been found in a fairly high northern latitude, they are also inhabitants of sub-Arctic climes, and are frequently seen as far south as latitude 54° in North America.

It is an established fact, although not, apparently, coming under the personal cognisance of Captain Sverdrup, that unmistakable traces of the odour of musk, which have had most unpleasant effects on those who have partaken of the meat so tainted, have on many occasions been observed by travellers and explorers, who, however, also report that their flesh when not tainted is excellent eating.

It is therefore to be regretted that Captain Sverdrup should have so completely ignored the experience of others, and substituted another name for an animal that is so well known, and one which has been in general use for so many years.

During the winter and following spring, several sledging expeditions were undertaken, having for their object the exploration of Ellesmere Land.

On one of these excursions Captain Sverdrup was unlucky enough to break one of his teeth, which incident is thus somewhat facetiously alluded to.

"When dinner was at last served, I fell to on a biscuit with such ardour that I managed to break off a front tooth. Fosheim (his companion) thought we ought not to waste our teeth so far away from people, and implored me not to go on in that way. I followed his advice, and was about to throw away the tooth, when he again observed, that there was no knowing how useful it might be; so I put it in my pocket to serve as a remembrance and a warning. I have since had it put in again."

Fosheim was evidently a man of a practical turn of mind, thoughtful, sensible, and of great perspicacity!

Although the Eskimos have never yet been found living on the western side of Smith Sound, vestiges of a previous occupation of the country by these nomadic tribes were discovered. They consisted chiefly of little heaps of stones and the ribs of whales placed in circular formations, presumably so arranged as to form their summer encampments. Similar traces, it may be remembered, were found by Sir George Nares's expedition on the west side of Smith Sound.

During one of his sledging expeditions in the late autumn, Sverdrup was startled by the altogether unexpected arrival at his camp of a sledge with two men on it. They proved to be the American explorer, Commander Peary, with an Eskimo dog driver. They had driven over from the ship *Windward*, which was beset in the ice about a mile from the shore in the neighbourhood of Cape Hawks.

This meeting on the silent shores of the Arctic Ocean seems to have been as surprising and as unexpected as the equally strange one between Nansen and Jackson in Franz Josef Land only a couple of years earlier. At that time they were probably the only two expeditions in the Arctic regions engaged on geographical discovery. They had been absent from home for a long period; they were several miles from their respective ships, yet we read, with something akin to surprise, that Peary only remained in their company for a few minutes, and would not even wait while a cup of coffee was being prepared for him, or, as Captain Sverdrup tersely puts it, "his visit was so short that we had hardly time to pull off our mittens"!

In the spring of 1899 the *Fram* was visited by several Eskimos from the east side of the Sound who were on their way to Peary's ship. They were so pleased with the warm reception that was accorded them, and with the kindness they received at the hands of the Norwegians, that they appear to have overstayed their welcome, for we read that:—

"We began to be heartily sick of them all. They spread all over the vessel a peculiar rank odour of blubber and train oil with indefinable additions. We tumbled over them wherever we went, while their shock heads of hair looked as if they might accommodate a legion of animals of which we stood in far greater fear than of either the polar ox or the bear"!

The wandering Eskimo is not altogether the most agreeable or the most savoury companion to associate with for an indefinite period.

It was not until the end of July that the *Fram* succeeded in extricating herself from the icy bondage in which she had been held for eleven long months. Attempts were at once made to work to the northward, but the ice was found so tightly packed that Captain Sverdrup abandoned all further efforts to proceed in that direction, and turned his attention to Jones Sound, a route that had always been regarded by Arctic authorities as one very favourable for exploration. On September 1 the *Fram*, having reached a position (in this sound) in the neighbourhood of Admiral Inglefield's furthest in 1852, was secured in her second winter quarters, in a small and almost land-locked harbour which was named Havnefjord.

From this position much useful and important geographical work was accomplished by boat in the autumn, and by sledges during the following winter and spring. Many musk oxen were fallen in with, and a large number of seals also were shot. The cold during the winter was so great that the brandy in a flask was frozen solid. The following little episode will show that inconveniences arising from intense cold were not regarded in a very serious manner by the travellers:—

"While Fosheim was taking his turn at running, being as warm as possible, he forgot all about his nose, which took this opportunity of freezing. He knew nothing about it, until it was frozen so stiff that it looked like a piece of white bone in the middle of his face, and he might easily have broken it off. Had it gone on freezing a little longer, he would have been noseless.

"However with general assistance and careful treatment that member was saved at the last moment, but it wore mourning for a long time afterwards, and looked more like a dab of pitch which had got into the wrong place than anything else in the world."

When released in the summer of 1900, the *Fram* steamed to the west and went up Cardigan Strait; after being beset in the ice for some weeks they succeeded in reaching the head of Goose Fjord, where they passed their third winter. They confidently expected that this would be their last winter from home; but, alas! the Fates ordained otherwise, and they were compelled to pass a fourth one, having only succeeded in

advancing during the summer a distance of nine miles, which brought them within five miles of the open water and freedom! It was, indeed, tantalising to know that such a short but impenetrable barrier intervened between them and the open sea. It will be remembered that it was exactly this distance of land ice that prevented our own ship, the *Discovery*, from being liberated after her first winter in the Antarctic regions.

In spite of their disappointment, the brave Norwegians did not in any way relax their efforts to carry out the important work entrusted to them, and much valuable information in various branches of science was obtained during their long sojourn in Goose Fjord, one of the sledging expeditions having attained the high latitude of 80° 30′, almost succeeding in reaching and joining hands with Aldrich's furthest in lat. 82° 16′ and long. 85° 30′ W. on the north coast of Grinnell Land.

It was August, 1902, before the little *Fram* was released from her imprisonment, reaching Norway the following month, where the gallant explorers received after their long absence that hearty welcome, not only from their own countrymen, but from the civilised world at large, which they so richly deserved.

On the whole the expedition achieved a great success. It added very materially to our geographical knowledge of the Arctic regions, especially in the neighbourhood of the Parry Archipelago. Captain Sverdrup cleared up satisfactorily the debatable question as to whether Hayes Sound had an outlet to the west, or whether it was, as many thought, only a large bay. The western limits of Ellesmere Land, Grinnell Land, and Grant Land were determined, a matter of some geographical importance, as illustrating the archipelagic character of the land on the western side of Smith Sound and Robeson Channel.

The scientific work accomplished by the expedition is contained in four appendices at the end of the second volume. Appendix i. relates to the geological investigations made during the voyage, and is of great interest. Appendix ii. is a summary of the botanical work of the expedition and its results. Appendix iii. refers to the fauna of the different localities visited by the explorers. The scarcity, it might almost be said the extinction, of the reindeer is ascribed to wolves; these voracious animals are the great enemies of all Arctic quadrupeds, except, perhaps, the polar bear and the musk ox. Four species of butterflies were found, as well as some moths and a few wasps.

Appendix iv. refers to the meteorological observations regularly taken during the whole four years.

Much literary skill is exhibited by the author in the compilation of this work. It is written in a popular manner, and imparts valuable information in an interesting and pleasing way.

It is a book that will certainly take its place among other standard works on the Arctic regions.

An excellent map of the regions explored will be found in a pocket at the end of the second volume.

AN IMPORTANT ARCHÆOLOGICAL DISCOVERY IN EGYPT.

THE most important archæological event reported from Egypt during the last excavation season (1903–4) is the discovery by Prof. Naville, of the University of Geneva, and Mr. H. R. Hall, of the British Museum, of the most ancient temple at Thebes. The excavations were carried on by Messrs. Naville and Hall on behalf of the Egypt Exploration Fund, which is to be congratulated on having made this important discovery. The services which have been rendered by the Egypt Exploration Fund to Egyptological science since its foundation, some twenty years ago, have indeed been innumerable.

One of the most important works carried out by the fund was Prof. Naville's complete excavation of the great temple of Deir el-Bahari, in the western hills of Thebes. The excavation came to an end in 1899, after the main temple had been entirely cleared and the necessary works of conservation and restoration had been carried out, but before the environs of the temple had been completely explored. To the south of the temple lay a wilderness of rubbish heaps, which might conceal a necropolis or even another temple, placed between the great shrine built by Queen Hatshepsut and the southern horn of the *cirque* of cliffs which rise behind and around Deir el-Bahari. Means for further excavation failed, however, and the exploration of the unexcavated tract to the south of the temple was postponed until the present season, when Prof. Naville again took up the spade and very soon discovered that underneath the heaps of rubbish (Fig. 1) lay the not inconsiderable remains of a smaller temple, of high archæological importance on account of its age.

FIG. 1.—Excavators at work on the Mounds.

It is the funerary temple or mortuary chapel of the most distinguished monarch of the eleventh dynasty, Nebkherurā Mentuhetep, who reigned about 2,500 B.C., according to the best authorities. A temple of this date is a great rarity in Egypt. Remains of even older ones (of the same funerary character) have been found by the German excavators, Messrs. Borchardt and Schäfer, at Abusir, near Cairo; these belong to the fifth dynasty and are at least five hundred years older than Prof. Naville's new temple; they are the most ancient temple remains in Egypt. The new temple, however, comes next to them in age, and if it is surpassed by them in peculiarities of architecture, it appears to fully equal them in general architectural interest and to surpass them in the point of artistic interest and importance, since it has added considerably to our knowledge of the history of Egyptian art.

The artistic triumphs of the Old Empire are well known; but our knowledge of the condition of art at the beginning of the Middle Empire under the eleventh dynasty was, until the present discovery, scanty. The general impression has been that the work of the

eleventh dynasty was rough and crude in style. The discovery in the new temple at Deir el-Bahari of hundreds of fragments of coloured relief sculptures of the eleventh dynasty compels us to modify this impression, and we see from them that, side by side with the somewhat crude and awkward productions hitherto considered characteristic of this dynasty, work of the highest excellence was also turned out. This is an important result, and it is by no means improbable that this improved artistic style is the work of a sculptor who, we know, lived in the reign of Nebkherurā, Mertisen by name, and his school.

These reliefs originally formed part of the decoration of the walls of the main pillared hall of Nebkherurā's temple. This hall, only a part of which has as yet been uncovered, stands upon an artificially squared platform of rock, immediately to the south of the Hathor shrine of the great temple of Deir el-Bahari, and separated from it by a small open court about sixty feet across. The platform is about fifteen feet high. Its sides were masked by a magnificent wall of finely-squared and fitted limestone blocks, built in bonded courses of

FIG. 2.—The Granite Threshold and Pillared Hall.

broad and narrow blocks alternately, one above the other, as may be seen from the photograph. In the extreme south-west corner of the court this wall is perfect. It is without doubt one of the finest specimens of Egyptian masonry yet brought to light. Entrance to the main hall on the platform was gained, as in the great temple, by means of an inclined ramp, which led up to an entrance gate, no doubt, like that of the main temple, a trilithon of red granite; the threshold of finely-polished red granite still remains *in situ* (Fig. 2). The socket in which the door turned (in the usual ancient manner before the invention of the hinge) is clearly seen, and also the small side run, or channel, by which the door could be bodily removed from the socket and replaced when necessary.

To the north of the ramp a colonnade of small, square sandstone pillars has been discovered, placed on a stone pavement immediately before and below the platform. It can hardly be doubted that a second similar colonnade originally existed to the south of the ramp. Thus we have the main portion of the temple, consisting of a pillared, or "hypostyle," hall of octagonal pillars placed on a platform of rock, approached by an inclined ramp, flanked by colonnades on the lower ground level. It will be noticed by all who have visited Deir el-Bahari that, so far as platform, ramp, and colonnades are concerned, this is precisely the arrangement of the great temple of Queen Hatshepset, or Hatasu, to the north. This opens up a new field of possibilities. The curious plan of the great temple has puzzled archæologists and architects from Wilkinson's time to the present day. Whence this curious arrangement of platforms, inclined planes, and colonnades, so totally unlike anything else in Egypt? Various theories have been propounded, but it is only now that the solution has been found, owing to the discovery of the temple of Nebkherurā. Colonnades, platforms, and ramps are then a feature of the older temple-architecture of Egypt; they were, at the time of the eighteenth dynasty, when the great temple of Hatshepset was built, old-fashioned, archaic, but it is evident that the great temple is, as far as its main arrangements are concerned, a mere enlarged copy of the thousand-year older temple at its side; it is simply a "magnificent archaïsm."

When it was built the older and smaller temple was still used as a temple, apparently, and both existed side by side for some time; this is shown by the fact that the later temple is not placed in the centre of the *cirque*, but is crammed up against the northern cliff-face; it could not be placed in the exact centre because the southern portion of the space at Deir el-Bahari was already occupied by the older temple. It was built roughly parallel to the older temple; it is oriented 24° S. of E. (Lockyer, "Dawn of Astronomy," p. 212), and this must be more or less the orientation of Nebkherurā's temple also. This fact is of interest, as the question might be mooted whether the orientation of the main temple is also an archaïsm, imitated from that of Nebkherurā's temple (B.C. 2500), or not. Sir Norman Lockyer has already postulated ("Dawn of Astronomy," p. 218) the existence in the western hills of Thebes of a temple of Hathor older than the shrine of the goddess at Deir el-Bahari, "built to observe the rising of the star [Hathor-Sothis, *i.e.* Sirius] at a time perhaps somewhat later than that given by Biot (3285 B.C.)." Nebkherurā's date is about 2500 B.C., but we have as yet no proof that in his funerary temple the reverence paid to his spirit was conjoined with a worship of Hathor. We may find this proof in the course of the further excavations, or the older temple of Hathor may have existed further to the southward, perhaps on the site of the present little temple dedicated to Hathor of the Waste at Deir el-Medina, which was originally founded in the reign of Amenhetep III., B.C. 1450. Certain it is that the worship of Hathor in the western hills is far older than the time of Amenhetep III. and Hatshepset, and the foundation of the oldest temple built in her honour at Deir el-Bahari or Deir el-Medîna may well go back to very near the date propounded by Biot for the first systematic observation of the heliacal risings of Sothis-Hathor (Sirius). It is to this very period—between 3285 B.C. and 2400 B.C.—that the beginnings of the Theban Empire and of the Theban temples must be placed. To the student of the astronomical orientation of Egyptian temples the new discovery will, therefore, be of the highest interest.

Among the large number of smaller objects discovered in the course of the excavations, the most interesting will probably prove to be the series of small *ex-votos* of devotees of Hathor, found in the court between the two temples. These consist of small cows (the sacred animal of the goddess), and female figures in earthenware and blue faïence, votive eyes and ears

in bronze and faïence, broken blue vases with representations of the holy cow emblazoned with stars, &c. These votive offerings, which nearly all date to the eighteenth dynasty, were undoubtedly originally devoted in the Hathor shrine of the great temple, and when the shrine became too full were thrown down by the sacristans into the space between the two temples, which thus became a dust-heap. And from this dust-heap many interesting objects have been recovered, including a copper chisel with hardened edge, which should be of special interest to metallurgists, and specimens of palm-fruit, nuts, reeds, and shells, dating to about 1500 B.C. One of the most remarkable objects found is a perfect three-cornered loaf of unleavened bread, of the same date. All these smaller objects, together with a number of specimens of the eleventh dynasty reliefs already described, will, we understand, be exhibited at the annual exhibition of the Egypt Exploration Fund at University College, Gower Street, in July next.

Subscriptions for the work of the Egypt Exploration Fund are much needed, and should be sent to the Secretary, 37 Great Russell Street, W.C. We are indebted to Mr. Hall for the photographs here published.

NOTES.

THE achievements of the Japanese in the war are causing increased attention to be given to the influence of brain-power on history. National enlightenment, and the scientific spirit which welcomes every increase of knowledge, are the two chief factors of progress in these days, and the Japanese successes have shown the power of both these attributes. An important article in the *Neue Freie Presse* of Vienna lays emphasis upon the use which Japan has made of its brain-power; and the following extract from a summary published in Monday's *Times* shows how the prediction made by Sir Norman Lockyer in his address to the British Association last year is being fulfilled:—" Japan has adopted modern civilisation with soul and body. She has not merely copied those externals of modernity which rob an uncivilised people of originality without giving any real value in exchange, but she has assimilated eagerly the ideas of modern culture. Modern are her schools, in which the children of all creeds are taught morals, but not religion, in order to avoid all ecclesiastical intolerance. Modern is her view that priests should refrain from political struggles, and should reserve themselves for the leading place in pious exercises. Modern is her wish, despite many a hard rub during the time of transition, to respect without prejudice all free-minded criticism of public affairs and not to crush opposition by brute force, or, worse still, to intimidate it by a system of crafty calumny. Modern also are her sincere respect for freedom of research, her joy in a conception of the universe which makes intelligence, not superstition, the regulating power of human acts, and greets with gladness every new discovery and every new thought; and modern is a policy which incites minds to development instead of fettering them, which favours instead of suppressing the sheer delight in material production."

A CONVERSAZIONE of the Institution of Electrical Engineers will be held at the Natural History Museum on the evening of Tuesday June 28.

THE death is announced of Dr. Max Kaech, officer in charge of the geological collections of the national museum of natural history and ethnography—the Museu Goeldi—at Para, Brazil.

A MEETING of members of council of the South African Association for the Advancement of Science was held at Johannesburg on May 19, Mr. T. Reunert presiding. The chairman reported that he had been in communication with the German, French, Austrian, and Italian Consuls, and was hopeful of the cooperation of these gentlemen in connection with the visit of Continental delegates to South Africa with the British Association next year. Dr. Pakes, referring to the impending departure of Mr. Reunert for England, mentioned that he would represent the South African Association at the forthcoming Cambridge meeting of the British Association.

THE Antarctic ships *Discovery* and *Morning* have sailed from Lyttelton for Plymouth.

THE Institution of Electrical Engineers visited Colchester on Saturday on the occasion of the formal reception and unveiling of an historical picture presented by the institution to the town of Colchester in commemoration of the tercentenary of Dr. William Gilbert, the "father of electrical science," who was born in Colchester.

IN connection with the St. Louis Exposition, an International Electrical Congress has been arranged from September 12 to 17. It will be divided into eight sections, for which the following have been appointed chairmen and secretaries respectively:—A, general theory, Prof. E. L. Nichols, Prof. H. T. Barnes; B, general applications, Prof. C. P. Steinmetz, Prof. Samuel Sheldon; C, electrochemistry, Prof. H. S. Carhart, Mr. Carl Hering; D, electric power transmission, Mr. C. P. Scott, Dr. Louis Bell; E, electric light and distribution, Mr. J. W. Lieb, jun., Mr. Gano S. Dunn; F, electric transportation, Dr. Louis Duncan, Mr. A. H. Armstrong; G, electric communication, Mr. F. W. Jones, Mr. B. Gherardi; H, electrotherapeutics, Dr. W. J. Morton, Mr. W. J. Jenks. It is at present intended to limit the number of papers to 150, and the transactions are expected to fill three octavo volumes. Mr. Elihu Thomson is president, and Dr. A. E. Kennelly, of Harvard University, general secretary of the congress.

THE annual general meeting of the Ray Society was held on June 9, Lord Avebury, president, being in the chair. The report announced the attainment of the society's sixtieth year; the death of two vice-presidents, Dr. C. H. Gatty, F.R.S., and Mr. R. McLachlan, F.R.S.; the completion of Newstead's "British Coccidæ" and of Michael's "British Tyroglyphidæ." The volumes to be issued during this year and next were stated to be:—Vol. i. of the "British Desmidiaceæ," by Mr. W. West and Prof. G. S. West; vol. i. of the "British Tunicata," by the late Joshua Alder and the late Albany Hancock; vol. i. of the "British Freshwater Rhizopoda and Heliozoa," by James Cash; and vol. ii. of the "Desmidiaceæ." The officers and council elected for the ensuing year were:—President, Lord Avebury, F.R.S.; vice-presidents, Dr. R. Braithwaite, Mr. A. D. Michael, and Lord Walsingham, F.R.S.; treasurer, Dr. DuCane Godman, F.R.S.; and secretary, Mr. John Hopkinson.

THE use that is being made of wireless telegraphy in connection with the war is shown by the following extract from a private letter received from the *Times'* operator at Wei-hai-wei, and published in Wednesday's issue:—" All the British warships, from the third-class cruisers up, are equipped with Marconi, about twenty-four in all; nearly all the Japs have wireless equipment; the Russian ships are equipped, and several German vessels. One or another of them can be heard any time, day or night. The Japs are

particularly numerous, and we are at it all the time. We laugh at them, for we have struck some good points in tuning, which settle them very nicely. On the boat, when receiving our stuff, two of the four wires are grounded directly, which gives best results. Any resistance between those wires and the ground weakens the signals. If we want to hear the Japs call, disconnecting ground wire entirely from syntoniser of the receiver brings them in strong; while with the ground wire on, as in receiving our stuff, the Japs come very faintly. On the shore station it is different. Three wires are best in receiving up to 100 miles, with the other two wires free, at which time the Japs come in weakest. By grounding the other two wires the Japs come in very strong and our stuff weakest. Above 100 miles our stuff comes best with two wires grounded directly. That, of course, allows others to come in, but they are not strong enough to prevent my reading through. So far, that tuning is best, and certainly gives very satisfactory results."

A REUTER message from New York states that Mr. Marconi's effort to supply news daily on board the Cunard liner *Campania* has been entirely successful. The daily news bulletin was issued to the passengers at breakfast. The *Campania* had not long started when news was received from the Seaforth station, and later in the evening from Poldhu. Touch was kept with the latter station until a distance of 2300 miles had been reached on June 9. At 2 a.m. on that date communication was established with Cape Breton, 2000 miles distant, and was maintained until the end of the trip. On June 8 Cape Cod station, 1030 miles distant, was picked up, Cape Breton and Poldhu being also in communication with the ship. On the following day news bulletins were received from the American stations. Communication was begun with Nantucket at 3 p.m. on June 10, news being received from that place as well as from Cape Breton and Cape Cod. In addition to the shore stations, communication was established with the *Etruria* and the *Aurania*. The *Lucania* exchanged news with the *Campania*, and a number of private messages were sent at intervals. Touch with both sides of the Atlantic was continuous for three days in mid-ocean.

WE learn from the *Pioneer Mail* that, through the initiative of Mr. E. H. Aitken, a zoological society is about to be founded in Sind with the object of promoting the study of animal life. The society will not aim at making collections of its own, but rather at improving those already existing in the municipal gardens and museum, and turning them to the best account for scientific purposes.

AT the suggestion of Prof. W. F. Barrett, Royal College of Science, Dublin, Mr. P. E. Belas described in NATURE of May 12 (p. 31) a simple method of showing vortex motion by allowing aqueous fluorescein to flow from a capillary tube with its point just below the surface of water in a tall cylinder, and then tapping the stand supporting the tube. Mr. Robert E. Doran, of Queen's College, Cork, writes to direct our attention to the fact that he has performed a similar experiment in his demonstrations for the past six or seven years. Mr. Doran recommends that a bulb be blown at one end of a glass tube, and that the open end be contracted to slightly less than 1 mm. bore. The bulb and tube are filled completely with a 1 per cent. solution of common salt to which fluorescein has been added to produce a liquid almost free from fluorescence. The tube is clamped vertically over the centre of a tall cylinder filled with water. When the water is at rest the tube is lowered until its aperture just touches the surface. This starts the experiment, and no tapping is necessary. Several photographs showing the vortex rings resulting from his method of procedure accompany Mr. Doran's letter.

IN *La Nature* of May 28, Dr. A. Hamberg, of Stockholm, gives an interesting account of his successful establishment of meteorographs on two mountains in Swedish Lapland. One set of apparatus, that shown in the accompanying illustration, is on the Portitjokko, at an altitude of 1850 metres, and has been working satisfactorily since July, 1902, with the exception of occasional interruptions of the anemometer owing to hoar-frost. The second apparatus is installed on the Sähkok, at an altitude of about 1080 metres. The barograph and thermograph were constructed by M. Richard, of Paris; the other instruments were made by Dr. Hamberg, with the aid of M. Linderoth, clockmaker, in Sweden. Each set of apparatus weighs 1000 kilograms, and the separate parts had to be conveyed by men and reindeer. The clocks go for a year, each "weight" being 300 kilograms. The recording portions of the meteorograph are encased in screens of sheet iron, inside which pans of calcium chloride are placed. The apparatus on the left of the diagram is the pluviograph. Instead of using ink,

which was found to be unsatisfactory, punctures are made every twenty minutes in the papers covering the drums of the instruments, and occasionally in the autumn the deposit of hoar-frost has to be cleared away by Laplanders. The great difficulties of the problem have only been overcome by Dr. Hamberg after persistent and tedious experiments, both as to position and methods of registration.

WE have received from the secretary of the Meteorological Office an excerpt paper containing some of the principal meteorological subjects dealt with in Section A of the British Association meeting at Southport. Among these is a paper on the general circulation of the atmosphere, by Dr. H. H. Hildebrandsson, being a summary of a report to the International Meteorological Committee (Upsala, 1903), which will attract attention. The author points out that while, thanks to the labours of Maury, Brault and others, the system of winds prevailing at the surface of the earth is well known, our knowledge of the motions of the upper currents gained from general publications is mostly based upon theoretical considerations. The late Rev. W. C. Ley commenced observations on the upper clouds in 1872, and in the following year the author established a series of cloud observations in Sweden with the object of determining the movements of the air at different altitudes in areas of high and low barometric pressures. These observations have been supplemented during recent years by experiments with balloons and kites. The result of these investigations, the author states, will render it necessary to abandon once for all the theory hitherto adopted of a

vertical circulation of the atmosphere between the tropics and the poles, and he expresses the hope that the terms "polar" and "equatorial" currents, which have hitherto caused so much confusion in dynamical meteorology, will disappear completely from meteorological science. In his important paper he shows, for instance, that in all parts of the temperate zone of the northern hemisphere an upper current from west to east prevails in all months of the year, while in the tropical zone the currents at all heights are almost without exception from east to west. Another important contribution, by M. L. Teisserenc de Bort, on barometric depressions at various altitudes, is contained in the excerpt above referred to, which corroborates the conclusions arrived at by Dr. Hildebrandsson.

THREE papers on terrestrial magnetism from the reports of the U.S. Coast and Geodetic Survey for 1902 and 1903 have just been received. In a paper on "Magnetic Observatories of the United States Coast and Geodetic Survey," Dr. L. A. Bauer and Mr. J. A. Fleming describe very fully the various points which have to be considered in determining suitable sites for magnetic observatories, and the question whether the elimination of magnetic material in the construction of observatories is essential when used only for observations of variations and not absolute values is discussed. A description of three observatories is given, and the paper is illustrated with maps of the selected sites and with views of the observatories and of the instruments used. A paper on "Magnetic Dip and Intensity Observations (January, 1897, to June 30, 1902)," by Mr. D. L. Hazard, gives full details of the magnetic elements determined at 800 stations—about one-fifth of the total number proposed for the general magnetic survey. In addition to the field observations, the variations of declination and of the horizontal intensity are recorded photographically at four observatories, at each of which the absolute values of the elements are determined at least once a week. Much difficulty was found in obtaining concordant results with different dip circles; subsequently an earth-inductor was selected as a standard dip instrument. In the third paper —"Results of Magnetic Observations made by the Coast and Geodetic Survey between July, 1902, and June, 1903" —Dr. L. A. Bauer describes the method of taking field observations, and gives tables of the results and a full description of each station used for the observations. It is evident that every precaution is taken that each station may be accurately located at any future date.

AMONG our weekly budget of pamphlets, we may refer to a copy of the *Proceedings* of the South London Entomological and Natural History Society for 1903, and also to one of the *Proceedings* of the Philadelphia Academy for April. The latter contains an important paper, by Dr. D. B. Castell, on the cell-lineage and larval development of the nudibranch mollusc *Fiona marina*.

MR. W. E. CLARKE has favoured us with a copy of a paper from the *Proceedings* of the Royal Physical Society of Edinburgh (vol. xv., part ii.) in which he describes, under the name of *Mus musculus faeroensis*, a new form of house-mouse from the Færöes. Large size and certain peculiarities in colour are the distinctive features of this race.

THE medusas of the Bahamas form the subject of the first issue of a new serial (vol. i., No. 1)—the *Memoirs of Natural Sciences*—published by the Brooklyn Institute. Compared with that of the Tortuga Islands, off Florida, the medusa-fauna of the Bahamas has been found by the author—Mr. A. G. Mayer—to be comparatively poor. This is accounted for by the circumstance that the Tortugas stand in "blue water," whereas the Bahamas are surrounded with shallow flats of coral-mud, very sterile in animal life generally.

AN important discovery with regard to the breeding of the cod is recorded by Mr. T. W. Fulton in the *Publications* (No. 8) of the International Council for the Exploration of the Sea. As a rule, cod spawn from January to June—chiefly in March—but some of these fish recently taken on a patch of rocky ground in the North Sea lying to the north-east of Aberdeen, off the coast of Norway, were found to be spawning in September and October. It was already known that the herring has a spring and an autumn spawning season, and now we have proof that, in one area at any rate, the same holds good for the cod. An interesting point for determination is whether there is any difference between the spring and the autumn fry.

DR. C. W. ANDREWS, of the British Museum, has recently returned from Cairo, where he had been studying the fine series of vertebrate remains from the Fayum district. A number of specimens have, we understand, been acquired by exchange for the British Museum, while the series in the museum of the Egyptian Geological Survey at Cairo has been arranged and developed by Mr. Barlow, jun., of the formatori's staff at the Natural History Museum, who went out some months ago for that purpose. Among the more important specimens at Cairo is a young skull of *Arsinoitherium zitteli*, exhibiting the cranial sutures, and thus permitting the identification of the bones from which the huge front horns arise.

FOR nearly twenty years Mr. F. M. Webster, of the Illinois Natural History Laboratory, has been endeavouring to find a means of mitigating the plague of "buffalo-gnats" (*Simulium invenustum*), which of late years have proved so disastrous to cattle-owners in the districts bordering the lower course of the Mississippi. The remedy is a simple, although somewhat expensive one, namely, to prevent the great river from overflowing its banks, for it is in such overflows that these noxious little flies breed, and thus overrun the country. That their ravages are no trifling matter may be gathered from the statement that in 1882 a farmer in Louisiana lost 3200 head of stock from their attacks. Wild animals are terribly tormented by these pests, and a white-tailed deer has actually been known to rush into a blacksmith's forge to obtain relief in the smoke from their bites.

A PAPER on "Fertility in Sheep," by Mr. F. H. A. Marshall (*Trans.* Highland and Agric. Soc., Scotland), directs the attention of stock breeders to certain points of practical interest which are discussed in a recent memoir by the author on the œstrous cycle in the sheep, published in the *Philosophical Transactions*, and noticed in NATURE of September 3, 1903 (vol. lxviii. p. 429). The paper concludes with suggestions for future investigations on fertility in the ewe.

MR. THOMAS BURLEIGH has published a second edition of Mr. E. F. Chidell's "Africa and National Regeneration" (pp. 78). The preface to the new issue occupies more than half the pages of the book.

THE list of spectroscopes and spectroscopic accessories just issued by Messrs. Adam Hilger, Ltd., is conveniently arranged, and supplies useful information concerning a great variety of instruments for general work and for special purposes. Among other interesting apparatus described we notice film replicas of Rowland's diffraction gratings with 14,438 lines per inch, and the Michelson echelon diffraction gratings with the number of plates ranging from ten to forty.

A SECOND revised edition of "An Elementary Geography of India, Burma, and Ceylon," by Mr. Henry F. Blanford, F.R.S., has been published by Messrs. Macmillan and Co., Ltd. The important changes which have been made in Indian geography since the appearance of the first edition of the book have caused the author to re-write several portions, and to add new chapters on the North-west Frontier Province and on the Laccadive and Maldive Islands.

WE have received from the Wentworth Publishing Co., of Surrey Street, W.C., a copy of their new "Seaside and Inland A.B.C. Holiday Guide." The book runs to 311 pages, and contains concise descriptions of all health and pleasure resorts and places of interest in the United Kingdom. Lists of all the golf links throughout the kingdom, of all British spas, of the principal angling stations, and of the coaching centres are also provided. This useful guide costs one shilling net.

ACCORDING to a communication of J. Knett which appears in the *Sitzungsberichte* (No. 11) of the Vienna Academy of Sciences, the thermal springs of Karlsbad deposit small yellow tabular crystals of barium sulphate which are distinctly radio-active, and show all the phenomena characteristic of the presence of an active element.

THE May number of the *Physical Review* contains interesting papers on "Potential Phenomena in Vacuum Tubes during the Production and Interruption of Electrical Discharge," by S. N. Taylor, and "Observations on the Radiation produced in an Alternating Condenser Field," by F. Sanford.

THE investigation of certain complex cerium compounds by Prof. B. Brauner, an account of which appears in the current volume, No. 39, p. 261, of the *Zeitschrift fur anorganische Chemie*, throws considerable light on the nature of certain cerium compounds which have been the subject of discussion for several decades. The red coloured salt which separates from the solution obtained by the action of water and sulphuric acid on oxide of cerium is shown to be the acid cerous salt of the complex cerisulphuric acid, and is represented by the formula

$$Ce^{iv}(SO_4)_4Ce^{iii}H.12H_2O.$$

Perfectly similar compounds, in which the trivalent cerium is replaced by lanthanum, neodymium and praseodymium, have also been obtained.

SOME interesting facts relating to the influence of the application of potash salts on the agricultural production of Prussia are contained in a recent address by Dr. Carl Ochsenius to the Philadelphia Academy of Sciences. In 1893 the consumption of potash in German agriculture was 60,000 tons, in 1903 it was 150,000 tons. The following numbers give the yields per hectare in kilograms of different kinds of produce for the two years in question:—

	Summer wheat	Summer rye	Summer barley	Oats	Clover and Lucerne	Hay
1893	1477	872	1517	1067	2249	2275
1903	2304	1023	1988	1837	5250	4056

THE existence of a urea-forming enzyme has recently been demonstrated by Kossel and Dakin (*Zeit. physiol. Chem.*, xli., 321, &c.). The enzyme occurs principally in the liver, but is also present in the thymus gland, mucous membrane of small intestine, kidney and lymphatic glands. It possesses the property of causing the rapid decomposition of arginine (δ-guanido-α-amidovaleric acid), which is one of the end products of tryptic digestion, into ornithine (αδ-diamidovaleric acid) and urea. The enzyme may be roughly isolated by precipitation of extracts of liver with alcohol and ether, or with ammonium sulphate, and may be preserved in the solid form for many months with but little change. The conversion of arginine into urea and ornithine illustrates a new type of enzyme reaction. The enzyme has been named "arginase," and is the first representative of the class of urea-forming enzymes capable of being isolated and of acting outside the body.

OUR ASTRONOMICAL COLUMN.

COMET 1904 *a*.—A new set of elements and an ephemeris for this comet are published in No. 3947 of the *Astronomische Nachrichten* by Prof. Strömgren. These vary but slightly from those previously published by Herr Ebert. Observations made on May 19 gave corrections of $-41s.$ in R.A. and $+2'.2$ in declination to the positions, for that date, derived from Prof. Strömgren's elements, thereby showing the latter to be fairly correct. From this fact it follows that the object which appeared on the Harvard photographs of March 11 and 15, which was thought to be this comet, must have been some other body, for its position is about 6° from the comet's position on that date as deduced from these elements.

The comet's orbit is probably parabolic, and is noteworthy for its large perihelion distance, somewhat similar to that of Giacobini's comet of 1902–3 (the *Observatory*, No. 345).

DURATION OF THE PERSEID SHOWER.—In a letter to the *Observatory* (June), Mr. Denning directs attention to the long duration of the annual shower of Perseids. He states that the shower is certainly active by July 19, and that it has not entirely ceased on August 16; there is some evidence that traces of it have been observed as early as July 7 and as late as August 25, a period of fifty nights.

Mr. Denning also gives a list of radiants for various stages of the shower, derived from the collected observations made during the period 1877–1903 inclusive.

Moonlight will not interfere with the observation of either the earlier stages (July 8–19) or the maximum and latest phases (August 6–19) of this year's shower.

FOUNDATION OF A NEW ASTROPHYSICAL OBSERVATORY.—A letter from Dr. C. Nordmann to the *Revue générale des Sciences* (No. 10, May 30) describes the aims and equipment of a new astrophysical observatory which has just been built near to Tortosa, in Spain, in latitude 40° 48′ N. and longitude 1° 47′ E. of Paris.

The general idea of the work to be prosecuted is to obtain information regarding the relations between solar and terrestrial phenomena, relations the existence of which has of late years been abundantly confirmed by all workers in solar physics.

Two magnetic houses have been equipped, the one for absolute measures of terrestrial magnetism, the other for obtaining records of the regular variations in the elements and of the extraordinary disturbances which appear to coincide, in point of time, with solar disturbances.

The observatory is also to be furnished with an equatorial for observing sun-spots, an Evershed photo-spectroheliograph, and an instrument for determining the radial velocities of solar prominence eruptions.

Another building has been set apart for meteorological observations and the study of atmospheric optics, and seismological observations have also been provided for.

THE TOTAL SOLAR ECLIPSE OF 1905.—In an article published in the *Popular Science Monthly* for June, Prof. W. W. Campbell gives an interesting *résumé* of what has already been achieved by eclipse expeditions, and indicates the present state of our knowledge regarding eclipse phenomena. He then suggests a number of observations which might be profitably made during the eclipse of May, 1905. Amongst these he considers the search for an intra-mercurial planet to be of prime importance. The observations of Perrine in 1900 seemed to negative the idea of such a planet's existence, but no *definite* conclusions could be formed owing to the intermittently cloudy state of the

sky at the time when the photographs were taken. Prof. Campbell suggests that cameras similar to those used by Perrine should be used in Labrador, Spain, Tunis, and Egypt. He also insists upon the necessity for setting up coronagraphs at each of these widely separated stations in order to determine whether or not any real changes take place in the corona during the eclipse.

The determination of the correct wave-length of the chief corona line is also suggested as being of great importance. Finally, he urges upon observers the vital importance of thoroughly testing all their instruments before leaving home, and of allowing themselves plenty of time to make the final adjustments whilst in the eclipse camp.

ACTUAL DISTANCES BETWEEN STARS.—By simple trigonometrical calculations, Mr. J. E. Gore has deduced some interesting facts regarding the probable actual distances between certain stars the parallaxes of which are known with some degree of certainty. Thus he has determined that Sirius and Procyon are separated by about half the distance between the former star and our own system, therefore Sirius as seen from Procyon would appear as a star of magnitude $-3{\cdot}08$. In the case of η and μ Cassiopeiæ, the actual distance between them is probably about one-fifteenth their distance from the sun, and their apparent brilliancies would therefore be about 225 times as great as they appear to us. In the case of double stars, these figures become much greater; for example, if we take 61 Cygni, the distance separating the components is about 55 astronomical units, and, as they are probably situated at some 515,662 astronomical units from the earth, their apparent brightness would be increased about 88 million times, or by 19·8 magnitudes, if seen at the distance which separates them. Similarly, the brightness of each of the components of α Centauri would be increased by 19·7 magnitudes (the *Observatory*, No. 345).

THE SUCCESSION OF CHANGES IN RADIO-ACTIVE BODIES.[1]

IT has been shown by Rutherford and Soddy that the radio-activity of the radio-elements is always accompanied by the production of a series of new substances possessing some distinctive physical and chemical properties. These new substances are not produced simultaneously, but arise in consequence of a succession of changes originating in the radio-elements. The radio-activity of these products is not permanent, but diminishes in most cases, according to an exponential law with the time. Each product has a distinctive rate of decay of activity, which has not, so far, been altered by any physical or chemical agency. The law of decay has been explained on the supposition that the product undergoes change according to the same law as a mono-molecular change in chemistry. The change occurs in consequence of the expulsion of an α or β particle, or both, and the activity of a product is thus a measure of its rate of change. While the products, like the emanations, and UrX, lose their activity according to an exponential law, the matter emanation X, which gives rise to the phenomena of excited activity, does not lose its activity according to a simple law. The experiments of Miss Brooks and the author, and of Curie and Danne, have shown that the decay of the excited activity of radium is very complicated, and depends upon the time of exposure to the exciting cause, viz. the emanation. The author has shown that the excited activity produced in a body by a short exposure in the presence of the thorium emanation increases at first for a few hours, passes through a maximum value, and then decays with the time according to an exponential law.

In the paper the curves of decay of excited activity of radium and thorium are given for both short and long exposures to the emanations, and it is shown that the law of change of activity with time can be completely explained on the theory that emanation X of thorium and radium is complex, and undergoes a series of successive changes.

The mathematical theory of successive changes is given in detail, and a comparison is made of the theoretical and experimental curves obtained for the variation with time of the excited activity. In the case of thorium, two changes are found to occur in emanation X. The first change is a "rayless" one, *i.e.* the transformation is not accompanied by the appearance of α, β, or γ rays. The second change gives rise to all three kinds of rays.

The decay of activity of emanation X of radium depends greatly on whether the α or β rays are used as a means of measurements. The curves obtained by the β rays are always identical with those obtained by the γ rays, showing that the β and γ rays always occur together and in the same proportion. The complicated decay curves obtained for the different types of rays, and for different times of exposure, can be completely explained on the supposition that there are three rapid successive changes in the matter deposited by the emanation, viz. :—

(1) A rapid change, giving rise only to α rays, in which half the matter is transformed in about three minutes.

(2) A "rayless" change, in which half the matter is transformed in twenty-one minutes.

(3) A change giving rise to α, β and γ rays together, in which half the matter is transformed in twenty-eight minutes.[1]

A similar rayless change is shown to occur in the "emanating substance" of Giesel.

The occurrence of a rayless change in the three radio-active bodies is of considerable interest. Since the change is not accompanied by rays, it can only be detected by its effect in the change or changes which follow. The matter of the rayless change is transformed according to the same law as the other changes. The rayless change may be supposed to consist either of a rearrangement of the components of the atom or a disintegration of the atom, in which the products of the disintegration are not set in sufficiently rapid motion to ionise the gas or to affect a photographic plate. The significance of the rayless changes is discussed, and the possibility is pointed out that similar rayless changes may occur in ordinary matter; for the changes taking place in the radio-active bodies would probably not have been detected if a part of the atom had not been expelled with great velocity.

The radiations from the different active products have been examined, and it is shown that the β and γ rays appear only in the last rapid change of each of the radio-elements. The other changes are accompanied by the emission of α particles alone.

Evidence is given that the last rapid change in uranium, radium, and thorium, which gives rise to β and γ rays, is far more violent and explosive in character than the preceding changes. There is some evidence for supposing that, in addition to the expelled α and β particles, more than one substance is produced as a result of the disintegration.

After the three rapid changes have taken place in emanation X of radium, there remains another product, which loses its activity extremely slowly. Madame Curie showed that a body, which had been exposed for some time in the presence of the radium emanation, always manifested a residual activity which did not appreciably diminish in the course of six months. A similar result has been obtained by Giesel. Some experiments are described, in which the matter of slow decay, deposited on the walls of a glass tube containing the emanation, was dissolved in acid. The active matter was found to emit both α and β rays, and the latter were present in unusually large proportion. The activity measured by the β rays diminished in the course of three months, while the activity measured by the α rays was unaltered. The active matter was complex, for a part which gave out only α rays was removed by placing a bismuth plate in the solution. The radio-active matter deposited on the bismuth is closely allied in chemical and radio-active properties to the active constituent contained in the radio-tellurium of Marckwald. The evidence, as a whole, is strongly in support of the view that the active substance present in radio-tellurium is a disintegration product of the radium atom. Since the radium emanation is

[1] Bakerian Lecture delivered at the Royal Society on May 19 by Prof. E. Rutherford, F.R.S.

[1] A statement of the nature of the three changes occurring in emanation X of radium was first given in a paper by Rutherford and Barne (*Phil. Mag.*, February). A brief account of the theory from which th results were deduced has been given in my book "Radio-activity" (Cambridge University Press). Later, Curie and Danne (*Comptes rendus*, March 14) arrived, in a similar way, at the same conclusions.

known to exist in the atmosphere, the active matter of slow dissipation produced from the emanation must be deposited on the surface of all bodies exposed to the open air. The radio-activity observed in ordinary materials is thus probably, in part, due to a thin surface film of radio-active matter deposited from the atmosphere.

A review is given of methods of calculation of the magnitude of the changes occurring in the radio-elements. It is shown that the amount of energy liberated in each radio-active change, which is accompanied by the emission of α particles, is about 100,000 times as great as the energy liberated by the union of hydrogen and oxygen to form an equal weight of water. This energy is, for the most part, carried off in the form of kinetic energy by the α particles.

A description is given of some experiments to see if the α rays carried a positive charge of electricity, with the view of determining experimentally the number of α particles projected from one gram of radium per second. Not the slightest evidence was obtained that the α rays carried a charge at all, although it should readily have been detected. Since there is no doubt that the α rays are deflected in magnetic and electric fields as if they carried a positive charge, it seems probable that the α particles must in some way gain a positive charge after their expulsion from the atom.

Since, on the disintegration theory, the average life of a given quantity of radium cannot be more than a few thousand years, it is necessary to suppose that radium is being continuously produced in the earth. The simplest hypothesis to make is that radium is a disintegration product of the slowly changing elements uranium, thorium, or actinium present in pitchblende. It was arranged that Mr. Soddy should examine whether radium is produced from uranium, but the results so far obtained have been negative.

I have taken solutions of thorium nitrate and the "emanating substance" of Giesel (probably identical with the actinium of Debierne) freed from radium by chemical treatment, and placed them in closed vessels. The amount of radium present is experimentally determined by drawing off the emanation at regular intervals into an electroscope. A sufficient interval of time has not yet elapsed to settle with certainty whether radium is being produced or not, but the indications so far obtained are of a promising character.

RECENT PUBLICATIONS IN AGRICULTURAL SCIENCE.[1]

THE United States Department of Agriculture has issued the fourth annual instalment of the great work upon which its Division of Soils has embarked, the detailed survey of the soils of the whole of the country. The area covered by the present report is little less than 18,000 square miles, which have been surveyed at a total cost of 12*s.* per square mile. The work is being carried on simultaneously in many parts of the States; the counties dealt with embrace some of the old settled eastern States like New York and New Jersey, the Carolinas and Virginia, the rich lands of Ohio, Kentucky and Illinois, also the recently settled districts in the Dakotas, Texas, Colorado and other areas of deficient rainfall, the Walla Walla wheat area on the Pacific slope, and the lately acquired dependency of Porto Rico.

The method adopted follows that of the earlier reports; a field party maps the distribution of the soils in each section and collects information as to the crops grown and their average yields, the conditions of labour and transportation, at the same time indicating the suitability of the land for new crops and systems of farming. Mechanical analyses of each type of soil are made at Washington and are set out in the report; occasionally chemical analyses are included; statistics of rainfall and mean temperature are also added.

The whole work is based upon the facts that different types of soil can be recognised and the areas which they occupy can be approximately mapped, and that particular crops and systems of farming can be associated with the various soil types, so that the agriculture of each area can be directed along the most appropriate lines and its farmers saved from many unprofitable experiments. While the volume contains no striking novelty, it is full of interest and instruction to the English student of agriculture or economics.

M. Tribordeau gives an account of the agricultural condition of the Pas-de-Calais, dividing it into regions based upon geological considerations of the nature of the subsoil. A description of each soil is given, generally accompanied by several analyses by M. Pagnoul; then follows an account of the agriculture, with reports in considerable detail of the system pursued on one or more farms of different sizes in the area. The varieties of each crop generally grown, the races of live stock, the yield, the conditions of labour, even the implements in use on each farm are carefully set out. The latter half of the volume deals more generally with the agricultural economics of the district, and discusses the position both financial and moral of the labouring class, the conditions of tenure, the societies and other means adopted for the encouragement of agriculture, particularly the spread of the movement for credit banks and cooperative associations. The work is liberally illustrated with maps, photographs and diagrams, and presents a valuable picture of the present critical condition of agriculture in western Europe.

The current volume of the *Journal* of the Royal Agricultural Society, which now appears annually only, is somewhat more exclusively occupied than usual with the work of the society. In addition to the usual prize lists there is a general account of the show held at Park Royal last June, another article on the machinery exhibited there, and a full discussion of the trials of wind pumping engines conducted by the society in 1903. Reports of committees and of the scientific officers of the society also bulk largely, including Dr. J. A. Voelcker's account of the experiments in progress on the farm at Woburn and at the Hills pot-culture station. Turning to the general articles, the interest that is being manifested in forestry is seen in the two opening papers; in one Mr. C. E. Curties treats generally of the management of British woodlands, and in the other Mr. R. Anderson deals with the utilisation of home grown timber and its bye products. Mr. Spencer Pickering describes his experiments at the Duke of Bedford's fruit farm at Woburn, which he has repeated on a different soil at Harpenden, on the ill effects produced by growing grass round apple trees.

The volume is completed by one or two statistical papers and an article by Mr. A. D. Hall on the manuring of grass land, in which he takes the Rothamsted experiments upon grass land as his starting point, and then proceeds to discuss the many other manurial experiments upon hay or pasture which are now in progress in various parts of the country.

MAIDSTONE MEETING OF THE SOUTH-EASTERN UNION OF SCIENTIFIC SOCIETIES.

THE ninth annual congress of the South-eastern Union of Scientific Societies opened on the evening of June 9, when Sir Henry Howorth, the outgoing president, resigned his seat to Mr. Henry Rudler, who delivered the annual address at the Town Hall, Maidstone.

Mr. Rudler alluded to his address as a string of commonplaces, but in it some very important topics were touched upon. He considered, for instance, the constitution of scientific societies, and the matters to be discussed at their meetings in these days of great specialisation. He divided the members of such societies as constitute the union into those (few in number) who do the work and those (the majority) who like to see what is being done. Mr. Rudler was of opinion that the latter should have their wants realised as well as the specialists, for to put it on the lowest plane, the societies generally depended upon the financial support of those intellectual people who take a general interest in the progress of science without aiding in it themselves. Mr. Rudler's advice was to hold sectional meetings for the specialists, where the matters to be considered might be as technical as occasion required, and to

arrange general meetings where scientific subjects were dealt with in a popular manner. The fact had to be remembered that many of the members came to the meetings after working hard all day, and with their brains more or less exhausted and in need of recreation.

Mr. Rudler also dealt with the craze for athleticism, which tended to lessen the ranks of the local societies and even of the British Association itself. He said that a party on a field excursion would get more physical benefit than a crowd of spectators watching competitions between professional athletes. He contended that the taste for "sport" of to-day was only a part of a large subject, the excessive love of pleasure. He said that different people had different ideas with regard to recreation, but that those who turned to natural history were exceptionally wise in their choice. Parents, and especially ladies, would, he suggested, do well to join a natural history society, if only as an example for the young, and to introduce them to a healthy atmosphere. Now that nature-study was successfully edging its way into our schools, there should be a fine crop of young naturalists in the making, and Mr. Rudler told the societies not to wait for the students to grow up, but to found branches for junior members.

After saying a word as to the secondary place that the results of the camera and the magic lantern should take in popular lectures, Mr. Rudler passed on to speak of the scientific work done by Maidstone men in the past, and to congratulate the town upon its museum.

On the morning of June 10 business was transacted, and officers and committee elected "For the Photographic Record and Survey of Kent," after a report of the work of the provisional committee had been read by Mr. H. Snowden Ward, who had acted as organising secretary.

Mr. F. J. Bennett, in a short paper, pointed out that the Kentish megaliths, like those in Wiltshire, follow lines which run from north to south, and this is also true in the case of earthworks and churches. A paper on the Lepidoptera of mid-Kent, by Captain Saville G. Reid, was taken as read, and the meeting concluded with some excellent suggestions by Mr. Bennett with regard to the utilisation of the twenty-five inch Ordnance maps by farmers. On these a plan of the drainage, the arrangements for which are often completely forgotten, could be entered, together with details of the work carried on from year to year. Mr. Bennett urged that such work should be secured by legislation, and the suggestion met with cordial approval. On the afternoon of June 10 there were two excursions; the first—geological and archæological—was to Aylesford, under the leadership of Mr. Whitaker and Mr. W. H. Benstead. The second was of a botanical and entomological character to the North Downs, under the leadership of Prof. Boulger, Captain Reid, and Mr. Elgar. In the evening the Mayor and Mayoress (Alderman and Mrs. Morling) held a reception in the Museum, Art Gallery and Technical Schools, which adjoin one another in a very convenient way. Afterwards the visitors had an opportunity of examining the Congress Museum, which consisted of specimens sent by members of affiliated societies, and arranged by Mr. E. W. Swanton. There were also on view nature-study exhibits from Kent schools to illustrate the paper to be read on the following morning. During the evening Mr. A. B. Harding read a paper on "Ice Streams and Ice Caves," and Mr. Paul Matthews described the possibilities of an artificial language, and gave an explanation of that which is known as "Esperanto."

On June 11 the election of officers took place. Prof. Flinders Petrie was elected president, and Dr. Abbott, to whom the union owes its origin, exchanged his office of honorary secretary with the Rev. R. Ashington Bullen for that of treasurer, which the latter occupied. The two vacancies on the council were filled with Miss Lawrence, of Reigate, and Mr. Wilfred Mark Webb.

When the last paper, which was on "The Teaching of Nature-study," was read by Mr. Wilfred Mark Webb, a number of teachers and pupil teachers were present through the efforts of the Kent County Education Committee and the local committee of the congress. Considerable discussion took place afterwards. Sir Henry Howorth supported the aim that the pupil should be made to ask why and to find out the answer for himself, and dwelt for some time on the advisability of studying animals in captivity. Prof. Boulger thought that nature-study should, in the case of young children, be correlated with poetry. Mr. Tutt pointed out the difficulties that occur in town schools, and urged the claims of more formal work than had been outlined, which savoured somewhat of science teaching. Mr. J. B. Groom, of St. Paul's Schools, Maidstone, who has made a speciality of rambles, begged the young teachers present to follow informal lines rather than those advocated by Mr. Tutt.

The number of societies now affiliated is forty-three, with upwards of five thousand members, while the funds of the union are in a satisfactory condition, and an invitation has been accepted to visit Reigate during 1905.

EDUCATIONAL CONFERENCE AT THE HORTICULTURAL EXHIBITION.

ON June 7 a conference was held at the Royal Botanic Gardens, Regent's Park, in connection with the educational section of the Horticultural Exhibition, which was open during the whole of last week.

Sir William J. Collins, chairman of the Education Committee of the London County Council, and president of the section, took the chair, and Mr. F. W. Verney read a paper on "Allotment Gardens and Working Men." In the course of this a good deal of stress was laid upon the need for teaching which would prepare country boys to work on the land, and a scheme for their education was mapped out. It seems to be generally recognised that if a boy is ever to do much good on a farm he must become acquainted with its working at an early age, and the compromise desired by Mr. Verney that a boy should be allowed to do some practical work on a farm before his school days are over would not only satisfy practical requirements, but would also probably keep the pupils under the influence of the schoolmaster for a longer period than is at present the case.

Miss Lilian Clark afterwards read a paper upon "Direct Methods of Studying Nature," such as are employed at the James Allen School for Girls, Dulwich. The papers which Miss Clark has read in the past at various science conferences have made us familiar with her work in garden and classroom, where real plants and not books are studied. It is interesting to be able to chronicle that a special room, which is a combination of laboratory and greenhouse, has been built as an aid to the experiments and observations which she directs.

Later in the morning Sir George Kekewich, who is president of the School Nature Study Union, gave an address on "Nature-study and its Cognate Educational Subjects." He made a special point of nature-study as a part of general education, saying that he would like to see it taught in every school in this country. The kind of training outlined was that now generally recognised as being really nature-study, and as Sir George Kekewich is one of those who think that the work, to be done properly, should be carried on out of doors, he spoke of the great difficulties which must exist in the case of most town schools. These difficulties would be all the greater if teachers felt, as Sir George Kekewich seems to do, that to keep animals in captivity (Sir George afterwards excepted canaries) is calculated to teach cruelty.

In the discussion the speakers were practically unanimous in disagreeing with the contention last alluded to. Mr. Hedger Wallace (honorary secretary of the section), Miss Kate Hall, and Miss Von Wyss were among those who thought that many animals could be properly studied "under control." The present writer expressed his opinion that as children see plenty of cruelty in their everyday life, it would be advisable to teach them kindness by keeping pets, and that if this were not done in nature-study, a great power for good would be thrown away.

Sir William Collins summed up nature-study; he said that it was not a new subject, though its recognition and the enthusiasm for it were new, and he emphasised the fact alluded to by Sir George Kekewich that it was not science teaching.

The opinion expressed by Sir George Kekewich that nature-study would not stay the rural exodus, and that its far-reaching effects would not be felt until other means

had been taken to stem the tide of emigration into towns, was not endorsed by the Rev. Claud Hinscliff, who, from his experience in Derbyshire, had come to a different conclusion.

Mr. J. Weathers, instructor in horticulture to the Middlesex County Council, read a paper on "Horticultural Teaching among Adults." His remarks referred mainly to the practical side, though in touching upon laboratory work he said that he believed in practice first and theory afterwards. Mr. Weathers also considered the question of allotments, and in the discussion which followed, Earl Carrington tellingly described from his own experience the advantages derived from small holdings by the tenants, by the landlords, and by the country at large. Mr. J. Martin White thought that a little theory was sometimes good to begin upon, and he pointed out the need for more attention to be paid in general to methods of cutting and keeping flowers for decorative purposes.

Mr. E. Caesar, headmaster of Hale School, Farnham, outlined in a paper "On School Gardens" the scheme of the Surrey County Council, and the work which had resulted in his own school holding premier place for four years running.

The last paper, on "School Nature-study," was by Miss Violet James, of Heidelberg College, Ealing. Miss James has tested the value of nature work, and not only has she discovered its powers for good, but has recognised the opportunities that exist for evil if the teacher pursues wrong lines.

WILFRED MARK WEBB.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—In convocation on June 2 the honorary degree of M.A. was conferred on Mr. F. A. Bellamy, first assistant at the university observatory.

Junior Scientific Club:—The ninth Robert Boyle lecture was delivered on June 3 by Prof. J. J. Thomson, F.R.S., on the subject of "The Structure of the Atom." On June 10 Dr. G. Mann, New College, read a paper on "The Importance of Salts in our Economy."

CAMBRIDGE.—In the mathematical tripos, part i., the senior wrangler is Mr. A. S. Eddington, Trinity. The second place is taken by Mr. G. R. Blanco-White, Trinity, and the third by Mr. F. J. M. Stratton, Caius.

PROF. J. W. GREGORY, F.R.S., professor of geology in the University of Melbourne, has been appointed to the chair of geology in the University of Glasgow.

THE following honorary degrees were conferred by Dublin University on June 11:—Doctors in Science, Prof. J. Dewar, Prof. J. H. van 't Hoff, Prof. Felix Klein, Major Ronald Ross, C.B., Mr. J. J. H. Teall, F.R.S., and Prof. W. H. Thompson.

DR. T. MARTIN LOWRY has been appointed lecturer in science at the Westminster Training College. Dr. Lowry will have charge of the whole of the science work of the college, and will also supervise the scientific instruction at the Southlands Training College.

MR. R. BLAIR, secretary in respect of technical instruction for the Department of Agriculture and Technical Instruction in Ireland, has been appointed executive officer for the performance of duties in connection with the administration of the Education Acts by the London Education Committee.

MR. JOHN D. ROCKEFELLER has, says *Science*, given to the Case School of Applied Science 40,000*l.* to be used for building and equipping laboratories for physics and mining engineering. Yale University will receive as residuary legatee more than 50,000*l.* from the estate of the late Mr. W. B. Ross, of New York City. The will of the late Prof. Maxwell Sommerville provides 4000*l.* for the preservation and care of the collection of engraved gems and ethnological collections given by him to the University of Pennsylvania some years ago.

AMONG recent appointments to professorships in American colleges announced in *Science* are the following:—Prof. C. Baskerville, of the University of North Carolina, to be professor of chemistry in the College of the City of New York. At Cornell University, Mr. D. S. Kimball to be Sibley professor of mechanic arts, in charge of the Sibley shops. Dr. R. Burton-Opitz to be adjunct professor of physiology in Columbia University, with a seat in the faculty of pure science. At the University of Nebraska, Mr. G. E. Condra to be professor of geology, and Mr. H. S. Evans to be an adjunct professor of electrical engineering.

IN the thirtieth general assembly of Iowa, it is stated by *Science*, an appropriation of 10,000*l.* was made for erecting either the first of a new series of engineering buildings or the wing of a single large engineering hall at the State University at Iowa City. An additional appropriation was made for constructing a dam in the Iowa River which will yield on the average more than three hundred horse-power. This power will be used for lighting and ventilating the university buildings, besides supplying power to the various engineering shops and laboratories. An additional 1000*l.* was appropriated for the better equipment of the bacteriological laboratory. Ground will at once be broken for a new museum building to cost about 25,000*l.* The present natural science building, completed in 1885 at a cost of 9000*l.*, will be moved bodily to a new site to make room for the proposed structure. The total income of the university for the next biennium will exceed 192,000*l.*, about one-third of which must be used for building.

THE Education Committee of the Essex County Council has decided to continue, during the course of the present summer, the Saturday afternoon demonstrations on field botany and other branches of nature-study which have proved highly successful in previous years. Two rambles will be held each Saturday during the remainder of June and throughout July. While these demonstrations are organised exclusively for school teachers, they are not intended only for those who have already studied botany; any teacher is eligible who takes an interest in general natural history. The same committee has decided to hold a holiday course in the principles and practice of horticulture at the biological laboratories and garden at Chelmsford for two weeks beginning on August 8. The object of the holiday course is to assist Essex teachers to gain a knowledge of the gardening operations necessary for the successful working of school gardens. The Essex Education Committee will defray travelling expenses once to and from Chelmsford, and will, in suitable cases, make a special allowance of 12*s.* 6*d.* per week towards the maintenance of teachers fulfilling the necessary conditions.

THE annual report of the council of the City and Guilds of London Institute for the year 1903 is a gratifying record of continued progress. The high standard of the work at the Central Technical College, at the college in Finsbury, as well as at the other special schools in different parts of London subsidised by the institute, has been well maintained. From the report of the examiners in the department of technology, it would seem that there is a decided improvement in the general character of the work presented, both in the written answers and the practical exercises; the most evident faults in the written parts of the examinations being due to the candidates' imperfect knowledge of the elements of physical science and of drawing, and to their inability to express their ideas in written language. It is certain that no great improvement in the intellectual character of the answers can be looked for until the teaching in elementary schools is made more practical, and further attention is given to training in drawing and scientific method and English composition. The large percentage of failures in all the preliminary examinations is an indication of the unprepared condition of the candidates on commencing their technological instruction. What the examiners in paper manufacture say is applicable to other subjects: "Without a previous attainment to a fair standard of mental training it is impossible either that a student can do justice to the technology of the subject, or have a ready habit of reducing his knowledge to expression."

It is to be hoped that the new code for the regulation of public elementary schools recently issued by the Board of Education, containing as it does a much broader and more scientifically planned curriculum, will remedy this defect, which has for many years hampered technical education in this country. It should be added that the report contains the inaugural address to the students of the Central Technical College, by Sir Guilford Molesworth, and also the address of Sir William White at the distribution of diplomas, &c., to the students of the institute's colleges and schools.

A CONFERENCE of headmasters and headmistresses, of representatives of midland educational authorities, and others interested in secondary education was held on March 19 last under the auspices of the University of Birmingham and the City of Birmingham Education Committee. The speeches delivered on this occasion have now been published in pamphlet form. The conference discussed two subjects at separate sessions. At the first meeting attention was directed to the training of secondary teachers—to what extent it is to be carried out (*a*) in training colleges, (*b*) in the schools themselves, and how far such training must depend on Government aid. The subject for the second session was the relative weight to be given to the humanities and to science in the various stages of secondary education. The remarks of some speakers in the discussion on the training of teachers for secondary schools showed that the belief in the necessity for training is not yet universal, though much more common than a few years ago. The headmaster of Shrewsbury, criticising the oft-repeated contention that the chief business of the secondary school is to train character, appropriately said:—"Is the day-school teacher—the secondary school teacher, I mean—to devote himself wholly to the formation of character, while at the same time England is falling into the rear in the matter of commerce and in scientific methods? We may concentrate our efforts on the formation of character until we forget how much more we have to do." The discussion on the relative importance of the humanities and of science was instructive as demonstrating the wide divergence of opinion which exists on most educational problems. Men of science will be disposed to agree with Sir Oliver Lodge, who said:—"I do not much care what is taught so long as it is taught well, and so long as the pupils learn what is taught. . . . I do not believe in having schools where boys having an aptitude for science shall learn nothing else, and schools where boys who have an aptitude for letters shall have nothing but a literary education." A complete education recognises the claims both of scientific and literary studies, and gives to each of these branches of knowledge its proper place.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, April 28.—"On the Changes of Thermoelectric Power Produced by Magnetisation, and their Relation to Magnetic Strains." By Shelford **Bidwell**, F.R.S.

The experiments described were undertaken with the view of investigating an apparent correspondence to which the author directed attention in an article published October, 1902 ("Ency. Brit.," art. Magnetism), between the effects of magnetisation upon thermoelectric quality and upon dimensions. Reference is made to the work of W. Thomson, Ewing, Chassagny, Houllevigue, and Rhoads. Although some of the results previously recorded appear to be erroneous, it is shown that, at least for iron and nickel, there is an intimate relation between the two phenomena.

In the case of iron, the relation is not disclosed unless allowance is made for the effect of the purely mechanical compression due to magnetisation. The author pointed out in 1888 (*Phil. Trans.*, vol. clxxix. A, p. 216) that a magnetised iron bar must be subject to a compressive stress, the consequent contraction being expressed as a fraction of the original length by the ratio of the lifting power or "tractive force" to Young's modulus. The tractive force was calculated in an earlier paper (*Proc.* Roy. Soc., vol. xlvii. p. 486). If a transverse cut is made in a longitudinally magnetised bar, the magnetic force inside the gap is $B=H+4\pi I$. One portion of the bar being fixed, the force acting upon the face of the other portion is less than B by $2\pi I$, the part due to the face itself; thus the attractive force per unit area $=(B-2\pi I)I=2\pi I^2+HI$. For permanent magnets, when $H=0$, and for the special case in which each half of the bar is surrounded by a tightly fitting coil, when the term $H^2/8\pi$ must be added for the mutual action of the coils, this expression becomes $B^2/8\pi$, which is sometimes said to represent "Maxwell's stress." The stress between any two portions of a magnetised bar divided by an imaginary transverse plane is sustained by the intermolecular springs, whatever their physical nature may be, to which the elasticity of the metal is due. Taking Young's modulus in grams per sq. cm. as 2×10^9, the extrinsic contraction due to magnetisation, expressed as 10-millionths of length, is $(2\pi I^2+HI)/200g$. Curves were plotted showing change of thermoelectric power and change of length in relation to H, and it was found that, if the latter were "corrected" for mechanical stress and the scale of ordinates suitably chosen, the two curves were almost coincident; without such correction there was no correspondence. The change of thermoelectric power due to magnetisation is therefore proportional to the "corrected" elongation, but the factor of proportionality differs for different specimens and for different physical conditions of the same specimen. It is shown in the paper that the two phenomena are analogously affected by tensile stress and by annealing.

For nickel it appeared, contrary to the accepted view, that the direction of the thermoelectric force was the same as in iron—from unmagnetised to magnetised through hot—whereas the "corrected" change of length is opposite in the two metals, iron being extended, nickel contracted. But the curves for change of length and for change of thermoelectric power were, when one of them was inverted, almost exactly coincident, although no correction was made for the mechanical stress. The question then arises, Why should the correction which is indispensable in the case of iron be unnecessary for nickel? The answer is that while for iron the calculated correction is very considerable (generally, indeed, greater than the observed change of length to which the correction is applied), for nickel it turns out to be exceedingly small; thus it happens that the uncorrected and the corrected curves, if referred respectively to slightly different scales of ordinates so chosen that the two curves may be of the same height, are sensibly identical. The absence of any need for the correction in the case of nickel, where, *a priori*, it ought not to be required, tends to show that the success of its application in the case of iron is not a mere accident, and the compressive stress is consequently a *vera causa*. Some years ago the question of stress in a magnetised metal was discussed by several well known physicists in NATURE (vol. liii. pp. 269, 316, 365, 462, 533), and it seems not to be agreed whether there is in fact any such mechanical stress; whether, supposing one to exist, it is compressive or tensile, and whether it is "Maxwell's stress" or some other. The author submits that the results of the new experiments support his original view.

For cobalt no relation between thermoelectric and dimensional changes attending magnetisation could be found; if any such exists, it is disguised by some cause which has yet to be discovered.

May 19.—"On Saturated Solutions." By the Earl of **Berkeley**. Communicated by F. H. Neville, F.R.S.

June 9.—"Notes on the Statolith Theory of Geotropism. I. Experiments on the Effects of Centrifugal Force. II. The Behaviour of Tertiary Roots." By Francis **Darwin**, F.R.S., and D. F. M. **Pertz**.

The facts given in the paper prove that when the primary root is removed and a secondary root assumes its place, the tertiary roots take on the character of normal secondaries. It may be believed, therefore, that the existence of statoliths in normal tertiary roots is a provision enabling them to assume diageotropic growth in case of injury to the primary root. This, though appearing a bold conclusion,

does not involve an adaptive action different in principle from the well known assumption by secondary roots of the characters of the primary root, although it is undoubtedly a more elaborate provision, and one which seems more unlikely to be called for in a state of nature.

Geological Society, May 25.—Dr. J. E. Marr, F.R.S., president, in the chair.—On the occurrence of a limestone with Upper Gault fossils at Barnwell, near Cambridge: W. G. **Fearnsides.** The limestone is variable in thickness, and is largely made up of comminuted shells of Inoceramus. It occurs in flattened lenticles. It contains abundant phosphate-nodules. Foraminifera, fragments of lamellibranchs, brachiopods, small gastropods, echinoids, and Crustacea are abundant. The fauna is not markedly different from that of the underlying clay. A list is given which shows that this fauna has been recorded from the Upper Gault of Folkestone. As these fossils are obtained 40 feet below the upper surface of the Gault seen in the section, it is clear that the whole of the Upper Gault of Cambridge was not used up in the making of the "Cambridge Greensand."—On the age of the Llyn-Padarn dykes: J. V. **Elsden.** The paper suggests that the bulk of the greenstone-dykes of this area belong to an earlier period of eruption than has been generally assigned to them. The greater part, if not actually of Bala age, seem to have been intruded before the post-Bala crush-movements. The evidence does not exclude the possibility that some of the intrusions may be of later date. Petrographical considerations make it impossible to separate these rocks from the diabase-sills of Bala age occurring farther to the south of this area.

Chemical Society, June 2.—Dr. W. H. Perkin, F.R.S., vice-president, in the chair.—The following papers were read:—Imino-ethers and allied compounds corresponding with the substituted oxamic esters: G. D. **Lander.** A description of the ethers obtained by the condensation of various bases with oxalic esters is given.—The action of heat on α-hydroxycarboxylic acids, part i., α-hydroxystearic acid: H. R. **Le Sueur.** The principal product obtained on heating this acid is margaric aldehyde.—Ionisation and chemical combination: J. Wallace **Walker.** The author shows that the assumption now generally made that all chemical action takes place between pre-existing ions is unjustifiable, in view of the fact that reactions such as those of the alkyl haloids with various compounds in presence of aluminium chloride take place under conditions under which ionisation cannot occur. Since ionisation is frequently the result of such reactions, he concludes that, in general, combination, as the result of the operation of higher valencies, precedes ionisation or any other manifestation of the occurrence of chemical change.—Ionisation and chemical combination in liquefied halogen hydrides and hydrogen sulphide: J. W. **Walker,** D. **McIntosh,** and E. H. **Archibald.**—Some compounds of aluminium chloride with organic substances containing oxygen: J. W. **Walker** and A. **Spencer.** These two papers give descriptions of compounds and experiments illustrating the arguments advanced in the first paper of this series.—The constituents of Chaulmoogra seeds: F. B. **Power** and F. H. **Gornall.** These seeds, which are derived from the plant *Taraktogenos Kurzii*, contain a cyanogen compound which is hydrolysed by an enzyme also present in the plant or by dilute acids into prussic acid and glucose, and may be a glucose-cyanhydrin. The fatty oil contained in the seeds furnishes on hydrolysis glycerol and phytosterol, and a number of fatty acids of which the most interesting is chaulmoogric acid $C_{18}H_{32}O_2$, which appears to contain a closed ring and one ethylenic linking.—The constitution of chaulmoogric acid, part i., F. B. **Power** and F. H. **Gornall.** A number of derivatives and oxidation products of this acid are described which have been prepared as a preliminary to the investigation of its constitution.—Gynocardin, a new cyanogenetic glucoside: F. B. **Power** and F. H. **Gornall.** This substance was obtained from the seeds of *Gynocardia odorata*, formerly believed to be the source of commercial chaulmoogra oil. It is crystalline, and is hydrolysed by an enzyme also existing in the plant furnishing prussic acid as one product.—*iso*Nitrosocamphor: M. O. **Forster.** A description of derivatives of this substance.—The basic properties of oxygen. Additive compounds of the halogen hydrides and organic compounds, and the higher valencies of oxygen. Asymmetric oxygen: E. H. **Archibald** and D. **McIntosh.**—The fermentation of the indigo plant: C. **Bergtheil.** It is shown that the fermentation in the indigo vat is produced principally by a specific enzyme.—The union of hydrogen and chlorine. Action of the silent electric discharge on chlorine: J. W. **Mellor.**—Studies on ethylcarboxyglutarate, part ii., action of ethyl bromocarboxyglutarate on ethyl sodiocarboxyglutarate. Formation of ethyl carboxyglutaconate: O. **Silberrad** and T. H. **Easterfield.**—The vapour pressures of liquid mixtures of restricted mutual solubility: A. **Marshall.** The vapour pressures of mixtures of water with various organic liquids have been experimentally investigated, and the results are discussed in the light of theoretical work on the same subject by Ostwald and others.—The influence of solvents on the rotation of optically active compounds, part v., the optical activity of certain tartrates in aqueous solution: T. S. **Patterson.** The rotations of a number of tartrates have been determined in aqueous solution at various concentrations and temperatures, and the influence of the latter on the numerical and sign value of the rotation is discussed.—The nitration products of the isomeric dichlorobenzenes: P. **Hartley** and J. B. **Cohen.** The authors find that the *meta*-law of substitution is followed, except in the case of *ortho*dichlorobenzene.

Linnean Society, June 2.—Prof. W. A. Herdman, F.R.S., president, in the chair.—Mr. A. O. **Walker** exhibited (1) viviparous plants of *Cardamine pratensis*, which phenomenon was unusually manifest this year, probably due to the abnormal rainfall, and (2) a gall on the flower-bud of the same plant, ascribed to *Cecidomyia Cardaminis*.—Mr. W. T. **Hindmarsh** exhibited photographs of the following plants:—*Primula deorum*, Velen., which he had succeeded in flowering, he believed for the first time in this country; *Shortia uniflora*, Maxim., the Japanese representative of the genus, with larger flowers than the original *S. galacifolia*, Torr. and Gray, and showing a tendency to vary in colour according to exposure; and *Rhodothamnus Chamaecistus*, Reichb., noteworthy for the abundance of its flowers.—*Papers*:—On the species of Impatiens in the Wallichian herbarium of the Linnean Society: Sir Joseph **Hooker.** The introduction described the material in question, consisting of 48 ticketed specimens out of 200 known species of the genus; though few in number, these specimens foreshadow the remarkable segregation of the species in the several phyto-geographical regions of India, which has no parallel in any other large genus known to the author. The second part of the paper consists of a detailed review of each sheet of the collection, with a critical determination of the specimens. There is one previously undescribed species, for which the name *Impatiens praetermissa* is proposed.—An account of the Chætognatha collected on H.M.S. *Research* in the Bay of Biscay in 1900: Dr. G. H. **Fowler.** *Sagitta serrato-dentata* was plentiful in the epiplankton down to the zone between 200 and 100 fathoms, with a maximum distribution about 50 fathoms; in daylight it appeared to rise to the surface, independently of the actual light-intensity of the moment; at night it left the surface for rather deeper water; even on bright moonlit nights, or during or after rain, it also deserted the surface, even in light daylight. The distribution of other species was described. In handling the Chætognath population as a whole, the author showed that it was thickest in the epiplankton, that below 100 fathoms there was a sudden drop in numbers, which continued down to the lowest depth studied (2000 fathoms), except for a possible slight local rise about 600 fathoms. This result, obtained by the accurate method of closing nets, directly contradicts the conclusion of Mr. R. T. Günther, deduced from the methods of open serial nets as used on the *Oceana*, that the population is greatest in deep water, the source of error with the open nets being introduced by the specimens captured during the net's upward journey to the surface from the depth nominally studied.—The flow of fluid in plant-stems: Prof. R. J. **Anderson.**

The experiments of the author were devoted to forcing water through woody stems, but references to the work of earlier investigators are not given.

Mathematical Society, June 9.—Prof. H. Lamb, president, in the chair.—The following papers were communicated:—Note on the application of Poisson's formula to discontinuous disturbances: Lord **Rayleigh**. Poisson's solution of the equation

$$\frac{\partial^2\phi}{\partial t^2}=a^2\nabla^2\phi$$

has the form

$$\phi=\frac{t}{4\pi}\int\int\dot{\phi}_0 d\sigma+\frac{\partial}{\partial t}\left(\frac{t}{4\pi}\int\int\phi_0 d\sigma\right),$$

where ϕ_0 and $\dot{\phi}_0$ denote initial values of ϕ and $\partial\phi/\partial t$ on a sphere of radius at, and the integration refers to angular space about the centre of the sphere. When the initial disturbance is continuous at the surface bounding the initially disturbed portion of the medium, the solution may be written in the form

$$\phi=\frac{1}{4\pi}\int\int\left(t\dot{\phi}_0+\phi_0+r\frac{\partial\phi_0}{\partial r}\right)_{r=at}a\sigma.$$

It is pointed out in the paper that, when there is discontinuity, the subject of integration in the latter form becomes infinite, and it is shown by an example how the integral may be interpreted so as to yield the correct result.—Wave fronts considered as the characteristics of partial differential equations: T. H. **Havelock**. It is shown that a wave front can be defined as a surface satisfying the principal equation of the characteristics of the equation of wave motion, and that, owing to the linearity of the latter equation, there is no necessity for the continuity of the first differential coefficients of the function expressing the disturbance, provided the function itself is continuous. The theory is extended to systems of partial differential equations, and, in particular, to the equations of propagation of electric waves. An invariantive property of characteristics is proved, and is applied to the theory of wave fronts and rays in moving media.—Illustrations of perpetuants: J. H. **Grace**. The quantic of infinite order being equivalent to a power series, the perpetuants are expressed as the results of performing certain operations of differentiation upon analytic functions represented by such series. It is shown that certain ones of the known analytic functions, such as the exponential function and the Weierstrassian sigma function, are determined by the vanishing of the simpler perpetuants.—Types of covariants of any degree in the coefficients of each of any number of binary quantics: P. W. **Wood**. A method is given for determining the type forms of the complete system mod $(ab)^{\frac{1}{2}n}$. The method consists in carrying out systematically a process indicated by Jordan, and previously applied to perpetuants by Grace.—Some expansions for the periods of the Jacobian elliptic functions: H. **Bateman**.

DUBLIN.

Royal Dublin Society, May 17.—Prof. J. A. McClelland in the chair.—Mr. J. H. **Pollok** read a paper on the extraction of glucina from beryl by fusion with caustic soda, solution in hydrochloric acid and saturation with hydrogen chloride to precipitate the alumina, the glucina and iron being afterwards separated by ammonium carbonate and sulphide. Analyses of carbonates, sulphates, and chlorides were also given that differed somewhat from theory.—Mr. F. E. **Hackett** read a paper on the n-rays. Some estimations of the magnitude of the subjective effects in the dark-adapted eye are given in this paper. It was found that bodies under strain produced an effect on a phosphorescent screen which could not be assigned to eye effects or the emission of heat.

PARIS.

Academy of Sciences, June 6.—M. Mascart in the chair.—On the parallax of the sun: Bouquet **de la Grye**. An account of the mode of working up the data from the photographic plates obtained in the French expedition for the observation of the transit of Venus in 1882.—On the photography of the superposed layers which constitute the solar atmosphere: H. **Deslandres**. A discussion of the work done with the large refractor at the Yerkes Observatory in relation to earlier results, together with some suggestions as to future work.—The accidental production of an intraliberian generating layer in the roots of Monocotyledons: Gaston **Bonnier**. A wound may provoke in the roots of certain Monocotyledons the commencement of secondary formations organised in the same manner as in a root of a Dicotyledon.—The physiological action of the emanation of radium: Ch. **Bouchard**, P. **Curie**, and V. **Balthazard**. The introduction of the radium emanations into the lungs of animals gives rise to toxic effects, the dominant lesion observed on *post mortem* examination being an intense pulmonary congestion. The tissues of the animals which have died under the action of the radiations are radio-active.—The radium emanation, *exradio*, its properties and changes: Sir William **Ramsay**. The emanation which escapes from radium bromide possesses the properties of a gas; it obeys Boyle's law, can be condensed at low temperature, and possesses an appreciable vapour pressure at the temperature of liquid air. The quantities available were extremely minute, about 0·0254 cubic millimetre, but this was found sufficient to prove the relation between volume and pressure, and also to obtain the spectrum. The gas is strongly luminous, but this grows weaker with time, and at the end of a month disappears. The gas appears to belong to the argon group, and has a density of about 80. If the molecule is monoatomic, the atomic weight would be 160, from which it would follow that one atom of the emanation is produced from one atom of radium.—The action exercised by the n-rays upon the intensity of the light emitted by a small electric spark, and upon some other feeble sources of light: R. **Blondlot**. A discussion of the views of M. Jean Becquerel as to the action of the n-rays upon the luminosity of a calcium sulphide screen, and an extension to the cases of a small electric spark and of a piece of platinum foil at a dull red heat.—On the emission of the n-rays and the n_1-rays: E. **Bichat**.—On the emission of the n-rays and n_1-rays by crystallised bodies: E. **Bichat**.—On the fifth scientific campaign of the *Princesse Alice*: Prince Albert of **Monaco**.—On expressions formed of superposed radicals: Paul **Wiernsberger**.—On the movements of solids with spherical trajectories: Jules **Andrade**.—On a variant of the universal joint: L. **Lecornu**.—On the critical velocity of directable balloons: Ch. **Renard**. It is shown that a balloon of the Santos-Dumont type must become ungovernable when the velocity approaches a certain critical value.—On the kathode rays: P. **Villard**. It is shown that the properties of the magneto-kathodic rays are inverse to those of the Hittorf rays; an electric field acts on the first like a magnetic field does on the second.—On a method of measuring coefficients of self-induction: M. **Iliovici**.—On the phenomena which accompany the contemplation in a dark room of feebly luminous surfaces illuminated by special kinds of light. The case of spots of phosphorescent sulphide; the effects of anæsthetics: F. P. **Le Roux**.—On the anæsthesia of metals: Jean **Becquerel**. Aluminium and copper lose their transparency to the n-rays when the surface which receives the radiation is submitted to the action of an anæsthetic; quartz appears to possess the same property. Glass, wood, and cardboard, on the other hand, always allow the radiation to pass through.—A method for the continuous registration of the state of ionisation of a gas: Ch. **Nordmann**.—The influence of the frequency in electrolysis by alternating currents: André **Brochet** and Joseph **Petit**. The electrolytic properties of alternating currents appear to be altogether different from those of continuous currents. The results obtained depend on the frequency of the alternations.—On the use of the n-rays in chemistry: Albert **Colson**.—On the reduction of o-nitrobenzyl alcohol. General remarks on the formation of indazyl derivatives: P. **Freundler**. The principal reduction products of o-nitrobenzyl alcohol are indazyl-o-benzyl alcohol, indazyl-o-benzoic acid, and anthranilic acid.—A new method for the preparation of anilides: F. **Bodroux**. The alkyl-magnesium compound is treated with an amine, and to the product an alkyl ester is added. From this, hydrochloric acid gives the anilide in a nearly theoretical yield. Details

are given of the cases in which the method has been successfully applied.—On humic manures: J. **Dumont.**—Study of the reaction brought about by an indirect oxidising ferment (anæroxydase): E. **Bourquelot** and L. **Marchadier.**—The destruction of the chrysalis of the silk cocoon by artificial cold: J. **de Loverdo.** The destruction of the chrysalis can be effected with greater certainty by cooling than by the usual method of heating.—On the apparatus for the collection of plankton: T. **Richard.**—On the Acarophytes: M. **de Wildeman.**—On barium sulphate from Lozère: M. **Guédras.**—On the platform of the higher summits of the Transylvanian Alps: E. **de Martonne.**—On seismic phenomena in northern Africa: F. de Montessus **de Ballore.**—On a volcanic eruption which took place in Arabia near the town of Medina on June 30, 1256: M. **Houdas.**—On the fossil flora of the Antarctic regions: A. G. **Nathorst.**—On the ergastoplasmic formations of the nephridial cells of sangsue (*Hirudo medicinalis*): Louis **Fage.**—Relation between the intensity of the reflexes and the nervous organisation: Ed. **Toulouse** and Cl. **Vurpas.**—Respiration in an atmosphere the oxygen of which is considerably rarefied is not accompanied by any modification of intraorganic combustions, as measured by the respiratory exchanges: T. **Tissot.**—The injection of phloridzine in the milch-cow: Ch. **Porcher.** The effect of the injection is to increase the amount of lactose in the milk.—Researches on the causes of natural immunity of snakes: C. **Phisalix.** The natural immunity of snakes is to be attributed to the presence of a free antitoxin in the blood which neutralises the poison as it penetrates into the circulation.—The agglutination of the red blood corpuscles by colloidal ferric hydrate, sodium chloride, and by different serums: Madame **Girard-Mangin** and Victor **Henri.**

Göttingen.

Royal Society of Sciences.—The *Nachrichten* (physico-mathematical section), parts i. and ii. for 1904, contains the following memoirs communicated to the Society:—

January 9.—P. **Drude**: The theory of light in "active" bodies.

January 23.—O. **Wallach**: Researches from the university chemical laboratory, xiii. (1) A new instance of optical isomerism. (2) The splitting of camphorphorone. (3) On 1:2:methylcyclopentanone. (4) On isoximes. W. **Biltz**: The relation of certain inorganic colloids to fibre with reference to the theory of dyeing.

February 20.—F. **Krüger**: The theory of electro-capillarity and of drop-electrodes.

March 5.—D. **Hilbert**: Principles of a general theory of linear integral equations (part i.). O. **Blumenthal**: Remark on the theory of automorphous functions. A. **Sommerfeld**: Contributions to the theory of electrons. (1) General investigation of the field of an electron moving in any manner. V. **Hensen**: The graphical process for deriving correct curves from the results of observations. W. **Biltz**: An attempt towards the interpretation of agglutination.

March 19.—W. **Nernst** and F. **von Lerch**: On the employment of the electrolytic detector in Wheatstone's bridge.

CONTENTS.

THURSDAY, JUNE 23, 1904.

THE LIFE WORK OF A SCIENTIFIC ENGINEER.

Original Papers by the late John Hopkinson, D.Sc., F.R.S. Vol i., Technical Papers. Edited by B. Hopkinson. Pp. lxvi+294. Vol. ii., Scientific Papers. Pp. vii+393. (Cambridge: University Press; London: C. J. Clay and Sons, 1901.) Price 10*s*. 6*d*. net each volume.

THREE years have elapsed since the two volumes of original papers by the late Dr. Hopkinson were published, and an explanation is naturally required for such a protracted interval being allowed to elapse before the work was reviewed in these pages. Shortly after its appearance, the writer became seriously ill, and the diminished vigour that accompanied a long tedious convalescence was marked by increased requests that work should be undertaken, exemplifying apparently the anecdote of the doctor who to obtain rest doubled his fees, but only succeeded thereby in doubling his practice. Hence the performance of a duty had to be postponed again and again, and it was not until Mr. C. S. Whitehead was kind enough to bring his mathematical power to bear on a critical analysis of this collection of papers and furnish the substance of much which follows that this tardy review came to be written.

In these two volumes we have the collected works of a man eminent not merely as a scientific investigator, but also as an engineer; they constitute the record of a worker who took a very leading part in showing his fellow electrical engineers how the application of scientific theory and knowledge helped more than crude trial and error in solving some of the numerous problems with which their industry abounds. Pioneers, as a rule, have the mortification of seeing their advances overlooked and neglected by their contemporaries, but Dr. Hopkinson had the happy fortune of being spared this; indeed, his papers resemble the writings of Shakespeare in that they appear to be full of quotations.

It might have been expected that a mathematician like Hopkinson, a senior wrangler and Smith's prizeman, would have freely used mathematical processes of some complexity, a transformer, for example, offering a most tempting field for mathematical excursion. But this is far from being the case; the great majority of the processes are such as can be easily understood by anyone moderately well versed in the calculus. But it must not be supposed that all these papers are easy reading; some of them are far from it, and it often takes considerable thought to grasp their meaning.

The first volume contains the technical portion of the papers, and opens with two dealing with lighthouses, one pointing out the advantages of what are known as group-flashing lights, the other describing the optical and electrical apparatus at the lighthouses of Macquarie and Tino.

The remainder of the volume deals almost exclusively with dynamo electric machinery. In the papers reprinted therein Dr. Hopkinson first shows how the curves now universally known as the "characteristic curves" are to be plotted, and then how to extract useful information from them; how, for instance, to determine the lowest speed at which a given dynamo can produce a short arc. He then directs attention to the necessity of taking account of both colour and direction in measurements of the brightness of the electric arc. A little further on we come to two papers on dynamo electric machinery, the first of which was written in conjunction with his brother, Dr. E. Hopkinson, in 1886. In these papers, which were published at about the same time as an equally important one on the same subject by Mr. Kapp, we are shown how the characteristic may be predetermined from theoretical principles based on the equations of a magnetic circuit, and on the magnetic properties of iron as found by experiment.

The paper of 1886 is classical, for with that of Mr. Kapp it laid the foundation of the design of electric machinery. Previously the proper shape to give to a dynamo was unknown, and it was impossible to foresee what effect on the performance of a dynamo would result from altering its shape. The late Prof. Rowland advocated long, lanky-legged machines, and Mr. Edison told the writer that the most astonishing thing in his life was finding that the dynamo which he sent to the Paris Electrical Exhibition of 1881 developed about the amount of electric power that he had hoped it might give.

Next follows the ingenious and economical method of testing the efficiency of a dynamo by coupling it mechanically to another of approximately equal size, and measuring the extra power that had to be supplied from an external source to keep the combination running when one of the machines acted as a motor and drove the second, which in its turn acted as a dynamo and supplied current to the first.

In reading through these papers one cannot fail to be struck with the keen insight which their author displays in picking out the essential points needing examination in the machine under discussion, and with the beautiful methods which he employs for presenting the results of his investigations. Thus, in his papers on the dynamo, he realised that, if the machine were to be improved by scientific study, it was absolutely necessary to ascertain, not merely how much power was put into it, and how much came out in a useful electrical form, but also what was going on in the various parts of the machine itself. Others before him had considered the input and output. Dr. Hopkinson, in conjunction with his brother, took up the second, and equally important, part of this investigation, and gave the results to the world in a manner that was as simple in expression as it was novel in conception.

The papers on alternating currents are, speaking generally, more important for what they suggest than for what they actually prove. Thus, to take those that deal with the parallel running of alternators. Two lines of argument in support of the opinion that they can do so are brought forward, one a purely

analytical method, the other proceeding from a consideration of the curves of current and E.M.F. If these two lines of argument rested on independent foundations, then their mutual agreement that alternators can so run would give weight. But, unfortunately, both proofs assume that the machines give smooth E.M.F. waves of the sine form and that the armatures have no iron, or, at any rate, that their self-inductions are constant. Further, the serious difficulty arising from "hunting" of the machines is not referred to. Hence the general conclusion, "You may therefore with confidence attempt to run alternate-current machines in parallel circuit for the purpose of producing any external effect," must be regarded as at any rate a bold one.

As a matter of fact, the two machines he experimented on did run in parallel perfectly, and others have since been built to do the same, but it does not follow, and indeed it is not the fact, that all machines possess this property. Dr. Hopkinson, of course, realised the limitations of his equations; indeed, he expressly mentions some of them. Hence in making his prediction we must conclude that he was more influenced by his experimental results than by his theoretical reasoning. In the numerator of the expression which occurs at the bottom of p. 149 of this paper

$$\frac{2\pi^2}{T} \text{ should be } \frac{2\pi}{T}^2.$$

A similar criticism as regards limitation in the reasoning may be passed on the equations used at the commencement of paper No. 10, p. 156, vol. i., on "Alternate Current Dynamo Electric Machines." Here he starts with the equation :—

$$Rx = E - (Lx)^{\cdot},$$

where the dot (left out by a printer's mistake on p. 163) signifies differentiation with respect to time. But, as Dr. Hopkinson remarks, "we do not know how L may vary," and so to obtain a solution he assumes L to be independent of time, which of course is not the fact, and so, as he points out, the ordinary theory does not fully account for the facts. This criticism, however, does not apply to the remainder of this paper, which is occupied with an experimental investigation of the currents induced in the coils and in the cores of the magnets of alternate current machines by the varying currents and by the varying position of the armature. A method of determining the efficiency of alternate current machines is also given, and the result used to show that in certain cases of relation of phase of current to phase of electromotive force, the effect of the local currents in the iron cores is to increase instead of to diminish the electromotive force of the machine.

We next come to a short but important paper in which the equations which hold in a transformer with a closed magnetic circuit are given and partially discussed; and in the next paper a method of testing transformers is described and illustrated, the method being similar to that previously given for continuous current dynamos

The remaining papers in this volume, consisting mostly of addresses, do not call for special remark, except for one paragraph, on p. 249, viz., "We know nothing of what light is; we do know that it is a wave." "Is it not infinitely probable that the waves of light are none other than the electrical waves which we know must exist, and must be propagated with the observed velocity of light? And, mark, this theory demands no ether." "Whether the postulate of an all-pervading ether be, or be not, a metaphysical necessity, surely it is well for the practical man and the physicist to leave the question to the metaphysician." Here, then, waves are allowed but an ether is denied, or looked on with suspicion, and so we have apparently to imagine a wave as independent of and apart from any medium; a vibration with nothing to vibrate seems a rather difficult conception. Nor is it easy to see what the metaphysician, in the proper sense of this much abused word, has got to do with the question of an ether; the physicist in his laboratory rather than the metaphysician in his armchair would seem to be the proper man to deal with it.

The papers in the second volume may be roughly divided into three groups. The first group contains papers dealing with residual charge and specific inductive capacity, the second group papers on the magnetisation of iron and the effect of temperature, whilst the third consists of papers on miscellaneous subjects.

The accurate determination of a physical constant of any substance is always a matter of scientific interest, but great additional interest and importance were attached to Dr. Hopkinson's experiments on specific inductive capacity from the fact that, according to Maxwell, the specific inductive capacity of a dielectric ought to be equal to the square of its index of refraction. To appreciate properly the full importance of these experiments we must remember that when Maxwell's treatise appeared in 1873, Maxwell was able to write that there was only one substance, paraffin, the capacity of which was known with sufficient accuracy for a comparison. To this solitary example Dr. Hopkinson added some four different kinds of glass and nine different oils, and it is hardly too much to say that if in all these substances the above relation had been fulfilled, then Hopkinson, and not Hertz, might have been regarded as the man who first experimentally verified Maxwell's theories, although Hertz's work would still have had its great value in connection with the actual propagation of electric waves in space. Unfortunately for Hopkinson, though the relation was found to be true in the hydrocarbon oils, in the vegetable and animal oils and in the glasses it was far from being satisfied.

So far, however, from jumping to the conclusion that Maxwell was wrong, Dr. Hopkinson, in a paper written in 1878, regards it as sufficient to add the caution, "it should not be inferred that his [Maxwell] theory in its more general character is disproved," whilst in a paper written in 1881 he remarks, "It must, however, never be forgotten that the time of disturbance in the actual optical experiment is many thousands of millions of times as short as in the fastest electrical experiment even when the condenser is charged or discharged for only the 1/20,000 second."

Further, in a paper published in 1882, he suggests that a further reason for the discrepancy as regards glass may be the fact that his experiments seem to show that glass would exhibit anomalous dispersion if the spectrum could be examined below the visible rays. Yet another reason for the discrepancy also suggested itself to Dr. Hopkinson, and this was the effect of residual charge, for he regarded capacity, residual charge, and dielectric conductivity, all as ordinarily known, as parts of one continuous phenomenon, and he assumes that we may add the effects of simultaneously, or successively, applied electromotive forces, and that residual charge is proportional to the electric forces producing it. He thus gets the expression:—

$$y_t = \int_0^{\infty} x\psi(\omega)d\omega,$$

where y_t is the displacement at a time t, x the P.D. applied at a time ω before t, and $\psi(\omega)$ is a function of ω only.

The experimental verification of this formula, and the detailed examination of various substances such as glass, ice, and castor oil, from this point of view are described in two exceedingly interesting papers. The influence of temperature on the phenomena is also examined. It appears from these experiments that the value of the specific inductive capacity of a substance depends on the time of contact. Thus Dr. Hopkinson found that the specific inductive capacity of ice when measured for periods of 1/100th to 1/10th second increases both with rise of temperature and with increase of time, and its value is of the order 80, but when measured for periods such as $1/10^6$ second its value is about 3, and he adds, "We conclude that the great deviation of ice from Maxwell's law is due to residual charge, which comes out between frequencies 10,000 and 100."

We may mention here that there are some misprints in the papers just referred to. On p. 15 equation (6) $\{X\psi(t) - B\}$ should be $X\{\psi(t) - B\}$; on p. 107, in equation (8), V^2/x should be V/x; on p. 113, a slight extension of the upper radius of the lower right-hand quadrant makes it appear as if this quadrant were joined to the right-hand top quadrant; and on p. 120, $dy_t/dt = \psi t$ should be $dy_t/dt = X\psi(t)$, and the reasoning that is given relatively to $\psi(t)$ really applies to $X\psi(t)$.

The magnetic papers commence with one on the magnetisation of iron, its value being greatly enhanced by the chemical analyses which are given of the specimens experimented on. An exact definition of coercive force is given, and the ascending and descending curves are found for a large number of samples by the split bar and yoke method. Attention is also directed to the way in which a small quantity of manganese changes the magnetic properties of iron; thus iron with 12 per cent. of manganese is practically non-magnetic.

The papers dealing with the effects of temperature on the magnetic properties of iron contain some very striking results. It had long been known that iron or steel became non-magnetic when raised to a sufficiently high temperature, viz. about 780° C. This Dr. Hopkinson calls the critical temperature, and he shows that for small magnetising forces the magnetisation of iron increases with rise of temperature until it approaches the critical temperature, but, on further heating, the magnetisation very suddenly almost entirely disappears. It is also shown that as conjectured by Barrett, recalescence occurs at the critical temperature, and that the quantity of heat liberated in recalescence is comparable with the heat required to melt bodies; and, as a further proof of the connection between recalescence and the disappearance of magnetism, Dr. Hopkinson shows that no liberation of heat takes place in a non-magnetisable manganese steel when experimented on in the same way as hard steel and iron.

Most remarkable results were found with certain alloys of iron and nickel. Thus it was found that a specimen containing 25 per cent. of nickel could exist in two different and quite stable states through a range of temperature from a little below freezing to 580° C., one state being non-magnetisable, the other magnetisable. Other physical properties of this alloy were found to change with its magnetic properties; thus its mechanical strength, its extensibility, its electric resistance, its density, are all different in the two states. From the memoir attached to the first volume we learn that Dr. Hopkinson tried if other substances, such as chromium and manganese steel, would behave in a similar manner when experimented on in the same way as the nickel and iron alloy, but none of them showed any sign of becoming magnetic, although cooled in solid carbonic acid.

Next follow papers on magnetic viscosity and on the propagation of magnetisation of iron as effected by the electric currents in the iron. It will be remembered with what interest the experiments on the latter subject were witnessed, and how, when the current was sent round the coil magnetising the block of iron, the ballistic galvanometers attached to the various search coils embedded in the mass deflected with considerable intervals one after the other as the magnetisation reached their respective search coils.

Lastly come papers on the rupture of iron wire by a blow, on the mathematical theory of Tartini's beats, on the effect of internal friction on resonance, on the optical properties of a titano-silicic glass, on the quasi-rigidity of a rapidly moving chain, on the torsional strain which remains on a twisted glass fibre after release from twisting stress, on the stresses caused in an elastic solid by inequalities of temperature, and various others.

At the present time, when so much attention is being given to the development of applied education in this country, it is instructive to look back on this ideal technical teacher, this translator of abstract mathematics into concrete industrial achievements, a man who was so able that he was quite simple and modest—for only mediocrity requires "side"—who sometimes spoke of things as having happened to be carried out by himself, as if it were a matter of mere chance that they had not been originated and accomplished by anyone else. What irony of fate when so many holiday-making Alpine tourists, whose only possible claim to notice consists in their having made some ascent a little earlier in the season or gone a little higher than someone else, return scatheless year after year, that the man who was doing, and had done, great work in

the realms of engineering practice and of pure science should have been lost to the world in his prime.

Vol. i is prefaced by a memoir written by his son—the present fitting holder of the chair of engineering at Cambridge—and this memoir, which even filial love and reverence have not made too flattering, forms the best review of the life's work of Dr. Hopkinson.

W. E. AYRTON.

REMINISCENCES.

Notes from a Diary. By Sir M. E. Grant Duff. Vol. i., pp. 317; vol. ii., pp. 326. (London: John Murray, 1904.) Price 18*s*.

SIR MOUNTSTUART GRANT DUFF tells us in his preface that in these two, as in the previous, volumes of his diary he has "resolutely kept to the less serious side of life." They contain no thrilling adventures, no sensational revelations, no acrimonious attacks, no profound metaphysical discussions. They give, however, an interesting picture of the life of a distinguished and cultivated man, with side glimpses of many of the most eminent of our contemporaries both in this and other countries.

For this Sir Mountstuart has had unique opportunities. When he was going to his Governorship of Madras his friends gave him a farewell dinner. It was a gathering of which any man might be proud, and in returning thanks for the toast of the evening, he said with no less truth than good feeling that, when he was young, his ambition had been to make friends of the best and highest of his contemporaries, and that, looking round him, he felt that in this object he had succeeded beyond his most sanguine hopes.

It is probable that many of those who read the diary will fancy that some pieces might have been omitted. I remember at one of our modest X club meetings we all thought that the dinner might be shortened, so as to give us more time for talk afterwards. But when we came to details we could not agree. One suggested to omit the soup, another the fish, a third the joint, and a fourth the pudding. Finally we remained as we were: so I fancy from the present volumes one would omit the botany, another the personal details, a third the theological hints, and so on. But if anyone is disposed to regard some of the details as hardly worthy of record, let him remember how interesting it would be now if Mecænas had left us similar details of his everyday life! What a light it would throw on Roman society and Roman history!

He gives us glimpses, moreover, which show the "art of conversation" at its best. He does not condescend to scandal, or attract attention by ill-natured remarks, or while away time by remarks on the weather. As Mr. Norton says in a typical case, "Flaubert's correspondence, a new edition of Æschylus, the Chanson de Roland, the management of the London Library, Bayreuth, the Euryanthe of Weber, were only a few of the many subjects which came up during our conversation."

The book is admirably adapted for a railway journey, a holiday, or a sick room. It is full of bright sayings, of good stories, of interesting reminiscences of interesting people. It carries us from one country to another, from one society to another: from London to Switzerland and Greece, from politics to theology, from The Club to the Athenæum or the Literary Society.

Sir Mountstuart thinks, and I should not be disposed to differ, that the late Lord Derby was the wisest statesman of his generation. At any rate, probably it would be safe to say that of those who took a leading part, probably none made fewer mistakes.

The botanical notes are numerous. He mentions, for instance, on the authority of Lord Plunket, that Westminster Hall is roofed with oak from the forest of Shillelagh.

The references to zoology are less frequent.

On p. 193 he tells us that Prof. (afterwards Sir William) Flower "gave a very interesting account of the shell of a tortoise which stands in one of the passages. Its original owner was a pet of Laud's, and lived in his garden at Fulham. When he became Archbishop he took the creature to Lambeth, where it lived from 1633 to 1753, when it came by its death, thanks to the folly of a gardener, who dug it up in the middle of winter."

He quotes Aubrey de Vere's happy saying that many people mistake downrightness for uprightness, and again that some people seem to "think they serve God but by serving their neighbour right."

Among other amusing bits are Sydney Smith's dream, "I had a very pleasant dream! I dreamt that there would be in future thirty-nine Muses and only nine articles"; the description of the French coinage of 1848 by a Royalist: "Liberté—point. Egalité—point. Fraternité—point"; which was thus varied: "Liberté de faire du mal. Egalité de misère. Fraternité de Cain et Abel"; the story of an Englishman who "was being driven by a carman through some town, when he saw in front of the Post-Office what he supposed to be the Nine Muses. 'What are those?' he asked his driver. 'The twelve Apostles,' was the answer. 'The twelve Apostles!' he rejoined; 'I can only see nine.' 'Oh,' said the man, 'the other three are inside sorting the Epistles:'"

Bradlaugh's saying with reference to the old and new trades unionism: "The motto of the old Trade Unionists was 'We will!' The motto of the new Trade Unionists is 'You shall!'"

One of the most beautiful of epitaphs, that written by Wordsworth (Bishop of St. Andrews) on his wife:

> I nimium dilecta: vocat Deus; I bona nostrae
> Pars animae; moerens altera disce sequi.

The names of Gladstone, Disraeli, Salisbury, Lowe, Coleridge, Newman, Stanley, Tennyson, Browning, Dufferin, Matthew Arnold, Huxley, and Flower are among those which flit through the pages. Sir Mountstuart says that he has dealt only with the less serious side of life. In saying so he meant, no doubt, that he does not deal argumentatively with politics, science or theology. The diary brings out, however, clearly his

sympathy with science, as shown, for instance, by his numerous references to botany and his many visits to the British Museum, his reverence for religion, and his affection for his friends.

He might have made his diary more piquant, no doubt, if he had yielded to the temptation of introducing some touches of that ill-nature which, as Lord Acton once said, makes the whole world kin. It is all the more to his credit that he has made a thoroughly enjoyable book quite free from scandal or bitterness

Many little indications scattered through the whole diary show how useful and sympathetic a part Lady Grant Duff has taken in her husband's career.

AVEBURY.

THE METHOD OF NATURE STUDY.

The Ludgate Nature Study Readers. Books i., ii., and iii. Edited by J. C. Medd. Pp. 176, 204, and 215.
The Frank Buckland Reader. Edited by F. T. Buckland. Pp. 248. (London: Routledge and Sons, Ltd., 1904.) Price 1s., 1s., 1s. 3*d*., 1s. 6*d*.

THE subject of "nature study" has occupied a pretty prominent place in educational discussions for the past few years, and now, for good or evil, seems to be established as a part of the routine of most elementary schools. For good or evil we say advisedly, since the subject is pursued with mixed aims and with very varied conceptions of what it can contribute to a child's education. Some people see in the subject a means of increasing the interest in agriculture and staying the migration to the towns, others regard it from a humanitarian and æsthetic side as teaching children to be fond of plants and animals; but the true function of nature study is to provide a convenient means of teaching the child to observe and experiment and so to apply its reason to the things among which it lives. Its only justification is that by its means the child can be made to work its own mind instead of passively accepting the statements of the teacher. As soon as the child's mind ceases to be actively finding out from the real object, as soon as the personal and actual note is lost, nature study becomes a very indifferent school subject.

The want of a clear conception of the spirit in which nature study should be pursued is somewhat apparent in the little series of readers which Mr. Medd has got together; they consist of a number of typical lessons contributed by men and women engaged in teaching all over the country, among whom we recognise the best of the exhibitors at the Regent's Park Nature Study Exhibition in 1902, which was so successfully organised by Mr. Medd. The subjects range over the whole scale of natural phenomena, wind and rain, the life of animals and plants, how to keep pets, rocks and fossils. We can recommend the book thoroughly to the teacher looking round for a subject to make his own, since with a little discrimination he will find examples of how to work and what to avoid. For example, in close proximity come two lessons about rocks; at p. 165, vol. iii., Dr. G. Abbot illustrates how the teacher should proceed to study the quarries in his neighbourhood (compare also Mr. Lewis, vol. ii., p. 192), what he can show from them about the way rocks have been made, and how they lead to general ideas about the structure of the country. A few pages further on we get the contrast—a tepid extract of text-book about strata, folds, dip, strike, &c., illustrated by diagrammatic sections of Kinekulle on Lake Wener, the Bavarian Hills, and the Schiefergebirge of the Eifel! Again, in the same volume, we get a lesson giving a wholly unilluminating account of sun-dials and the apparent motion of the sun, which would leave the ordinary child dazed with east and west, hour lines and shadows. What is anyone to make of an explanation like the following:—

"Now, when the ancients found out that the reason the time of sunrise varies is because the earth's axis is tilted, it occurred to them to make the gnomon lean in the same direction. The result of this was that the shadow fell on the same hour lines at the same time of the day all the year round. What a splendid discovery!"

The next lesson is a good example of the right method; the children learn to follow the change in altitude of the sun throughout the year by marking its height on a window-pane, the motion on the floor of the shadow of a spot on the same window being also recorded at the same hour every day. Little by little, as the child absorbs facts of this kind, the motion of the earth and its consequences as explained by the teacher will begin to live in its mind.

It cannot be too often repeated that as soon as nature study leaves the path of actual observation and experiment it not only becomes valueless educationally, but it is apt to result in howlers. Popular natural histories abound in hoary untruths, some of which are handed on another stage in these pages; some again seem to be newly invented. Take the following statement, vol. iii., p. 52:—

"The experienced eye can detect at once whether any particular soil is, or is not, deficient in iron by the colour of the vegetation. Compare the grass growing on chalk downs with that in a rich, alluvial valley even in the same locality. The former is short and stunted, no matter how wet the season may be, and it never attains the deep, rich green hue of the latter, inasmuch as chalk contains very little iron, and that as an impurity."

Sciolism could not go further; we should like to *viva* the author on the meaning he attaches to the word "impurity" in this connection, but he, alas! is an inspector, born to *viva* other people!

As regards the way to treat natural history proper in the school and how to turn the child's strong instinct for collecting into the right lines, no better lessons could be found than those on insects provided by Mr. W. J. Lucas.

The fourth volume of the series consists of a selection from Frank Buckland's "Curiosities of Natural History," and makes as good a school reading book as one could wish to have. The whole series is well printed and liberally, if somewhat unequally, illustrated.

A. D. H.

OUR BOOK SHELF.

On the Location and Examination of Magnetic Ore Deposits by Magnetometric Measurements. By Eugene Haanel. Pp. ix+132 and plates. (Ottawa, Canada: Department of the Interior, 1904.)

DR. HAANEL, Superintendent of Mines to the Canadian Government, read a paper under the above title at the annual meeting of the Canadian Mining Institute in the spring of last year, which is now published in book form by direction of the Minister of the Interior.

The work is substantially an account of the Swedish method of locating by means of specially constructed magnetometers the presence of magnetic ore deposits, and of determining their strike, direction of dip, and depth below the surface.

Von Wrede, as far back as 1843, indicated the value of the magnetometer in determining the location and extent of such deposits, but the first to turn the suggestion to practical account was Robert Thalén, who, in 1879, published his work "On the Examination of Iron Ore Deposits by Magnetic Measurements." Since that time the method has been greatly developed, and convenient field instruments—the Thalén-Tiberg magnetometer and the Thomson-Thalén magnetometer—are now placed by Swedish mechanicians at the disposal of mining experts. As yet, however, the knowledge and use of these instruments have been almost exclusively confined to Sweden, although scattered references to their employment are to be met with in English mining and scientific literature.

Rücker and Thorpe, in their great magnetic survey of the British Isles, showed the value of the magnetometer in determining the presence and the contour of underground magnetic material, and they were the first to direct the attention of English geologists to the importance of this instrument in geological inquiry.

Dr. Haanel has rendered the mining profession a great service by putting together a concise account of the Swedish method and practice. By the help of this manual a properly trained mining engineer would have comparatively little difficulty in mastering the theory of the field instruments and in acquiring familiarity with their use.

Whether, however, the greater number of English mining engineers are sufficiently well trained to follow the mathematical treatment of the theory, as set forth by Dr. Haanel, may be open to doubt.

Spokil, an International Language. By Dr. Ad. Nicolas. Pp. viii+272. (Paris: A. Maloine, 1904.)

THIS work consists of eight pages of preface, of eighteen pages of "grammar," of forty-four pages of exercises, and of 203 pages of a "Spokil"-French dictionary. The language consists of two kinds of words; those borrowed from existing languages with slight modifications and those coined on a system. The system is ingenious, but, in the opinion of the reviewer, quite unworkable. To take an instance:—To the letter "P" is attached various ideas; for example, those of motion, the foot, weight and the preposition "after." Thus we find Pimo, heavy; Pino, light; for the letter n contradicts the letter m; Peme, to lead; Pene, to come; the idea of "leading" being antithetical to that of "coming"; Pleal, wood; and Plealta, absence of wood; the idea of absence or default arising from the affix "ta"; and so on. As in Esperanto, different parts of speech are distinguished by different vowels, as, for example, Arta, dirt, or a dirty object; Arte, to dirty; Arto, dirty; and Artu, dirtily. The language is in what may be termed the agglutinative stage; for we have Apafil, derived from Ap, to lead, af, off, and il, agent; the whole word means an abductor. It may interest chemists to know that the future name of butylene is to be eul vokilo; for e stands for carbon, u for hydrogen, l is terminative; vo means four, ki eight, and lo is the termination of a noun (?). English plurals in s are borrowed; likewise our classification of genders. The definite and indefinite articles are retained in the singular and plural, the latter in the plural in the sense of "the ones"; and the French "du" and "des" also appear in both numbers.

Enough has probably been said to give an idea of the character of the grammar; in conclusion, we will show what is "to serve as a model to future speakers"; it is "Zu erve di teil da les espel zoio." We do not think that that will be the fate of this artificial language. And it may be confidently supposed that the future universal language will not be invented by a Frenchman. There have been a good many attempts; and they all tend far too much towards inflection. Probably the most perfect languages from that point of view are those of the native Australians, who possess singular, dual, trial and plural, who have inclusive "we" and "they," as well as exclusive, and who indicate in half-a-dozen ways the particular position of the object designated by the word "that." The idea of an international language is an admirable one, and it will no doubt be realised, but the end is not yet come, and it is certainly not "Spokil."

The Non-Metallic Minerals: Their Occurrence and Uses. By George P. Merrill. Pp. xi+414. (New York: John Wiley and Sons, 1904; London: Chapman and Hall, Ltd.) Price 17s. net.

THE author of this valuable work is head curator of geology in the United States National Museum, and in 1901 he issued a scholarly guide to the study of the collections in the section of applied geology. Upon this guide he has founded the present work in which he brings together the widely-scattered notes and references relating to the occurrence and use of minerals of value other than as ores. Much of the information he gives is quite new, particularly in regard to the occurrence of American minerals; and the value of the work is greatly enhanced by the well-selected photographs of quarries and of striking specimens. Among these the views of the big vein between the peridotite and gneiss at Corundum Hill, North Carolina; of the quarry of lithographic limestone at Solenhofen, Bavaria; of large spodumene crystals in granitic rock, Etta Mine, South Dakota; and of quarries of bituminous sandstone in California and in Indian territory, are of special interest.

The scheme of classification adopted is as follows:—(1) Elements, (2) sulphides and arsenides, (3) halides, (4) oxides, (5) carbonates, (6) silicates, (7) niobates, tantalates and tungstates, (8) phosphates and vanadates, (9) nitrates, (10) borates, (11) uranates, (12) sulphates, (13) hydrocarbon compounds, and (14) miscellaneous, including grindstones, pumice, moulding sand, road-making materials, &c. Gems, building stones and marbles are not included in the scheme. Under each species will be found an excellent bibliography, and much interesting comment and information regarding its uses. For example, we are told that at Oberstein, on the Nahe, schoolboys' marbles are made in great quantities from limestone. The stone is broken into square blocks, which are thrown into a mill consisting of a flat horizontally revolving stone with numerous concentric grooves on its surface. A block of oak, of the same diameter as the stone and resting on the cubes, is then made to revolve over them in a current of water, the cubes being thus reduced to the spherical form in about fifteen minutes.

Of lithographic stone a series of analyses are given

showing the variation in composition, even in samples from the same locality. The only stone which has as yet been found to fill all the requirements of the lithographer's art is that from Solenhofen, in Bavaria. In the United States materials of the nature of lithographic stone have been reported from a number of localities described by the author. While, however, it was possible to get small pieces suitable for trial purposes, every locality has failed, as a constant source of supply of the commercial article. Very encouraging reports come from Canadian sources, and it is possible that a considerable lithographic stone industry may yet be developed in the Dominion.

Essais des Metaux, Theorie et Pratique. By L. Gages, Chef d'escadron d'Artillerie. Pp. 168. (Paris: Gauthier-Villars, no date.) Price 3 francs.

This little work, the sixth of the "Aide-Memoire" series on metals, by the same author, is written with much of the charming clearness of diction generally found in French metallurgical writings. There are two parts, the first on the theory of the tests and the second on practice. Considering the size of the page (convenient for the pocket), the matter is wonderfully well treated. Thus, to take the tensile test as an example, there is a general heading, Preliminary Ideas, with paragraphs (1) Period called Elastic, (2) Period of Deformation, (3) Contraction, (4) Curve of Traction. In this last is worked out from the ordinary tensile curve, showing elongation and tons per square inch on the original section, a curve showing tons per square inch on the real section, thus making plain to the student the reason for the apparently paradoxical form of the ordinary curve. The next main heading is the Law of Similitude, treated under six subheadings, the first of which, for example, considers the two permanent elongations produced during tensile testing. These two very distinct elongations are not only made clear, but methods are given for their determination, and the steps in the reasoning are worked out by simple mathematical methods where necessary. In like manner are handled such subjects as elasticity, influence of temperature, repetition of stresses, distribution of deformations, augmentation of elastic limit.

Part ii., on practice, treats in a general way of the tests applied by engineers before accepting cast-iron, steel, steel castings, &c. A short chapter gives a general idea of the kind of tests applied to metals other than the iron family. Two pages on microscopic metallography are full of wisdom, counselling caution in its use alike for specification and deduction, which might well be taken to heart by some present day advanced workers. If one remembers that the little book is of a very general nature and deals with ideas about tests and testing with few details, then it is heartily to be recommended.

A. McW.

Karl Heumann's Anleitung zum Experimentiren bei Vorlesungen über anorganischen Chemie. By Dr. O. Kühling. Third edition. (Brunswick: Vieweg und Sohn, 1904.) Price 19 marks.

So long as the lecture system of imparting information is retained, so long will the experimental demonstration remain its necessary accompaniment. It is useless to contend that a student cannot derive the advantage by seeing an experiment performed that he would were he to do it himself in the laboratory. Apart from the costliness of much of the apparatus, the difficulties of manipulation would put it beyond the power of a beginner to obtain satisfactory results, which depend, as they frequently do, on the skill and experience of the experimenter. Provided an experiment is neither merely pretty nor obviously sensational, nor lasts long enough to interrupt the train of ideas, the effect can only be stimulating to the student. But the effective lecture experiment fulfilling these conditions requires a good deal of thinking and working out, and that is why the books on lecture experiments by Heumann and Newth are invaluable to teachers whose time outside the lecture room is occupied with research or the manifold duties of their departments. The third edition of Heumann's "Anleitung zum Experimentiren" will be welcomed by all teachers of chemistry. The author, who is perhaps better known as the discoverer of the indigo synthesis, died in 1894, shortly after the second edition of his work appeared, and the task of revision has fallen to Dr. Kühling. The experiments which he has added relate to electro-chemistry, to the use of liquid air in low temperature experiments, and to Moissan's electric furnace and Goldschmidt's reduction methods for the production of high temperature reactions. Physical chemistry also claims a small share of the new edition. The increasing use of the lantern has induced the editor to introduce a chapter on optical projection which includes an account of an electric installation for the lecture room. The author has had the advantage of obtaining much valuable information from such skilled experimenters as Landolt, Fischer, Buchner, Bunte and many others, with the result that the volume has swelled to a bulk which might dismay any ordinary lecture assistant.

J. B. C.

Church Stretton. Vol. ii. *Birds*, by G. H. Paddock; *Flowering Plants*, by R. de G. Benson; *Mosses*, by W. P. Hamilton; *Parochial History*, by H. M. Auden. Pp. 205+xvii. Vol. iii. *Pre-Roman, Roman, and Saxon Archaeological Remains*, by E. S. Cobbold; *Church Architecture*, compiled by E. S. Cobbold. Pp. 124+x. Both volumes edited by C. W. Campbell-Hyslop and E. S. Cobbold. (Shrewsbury: L. Wilding, 1904.) Price 5*s.* net each.

The first volume of this instructive guide to Church Stretton, which is now complete, was reviewed in our issue for October 11, 1900 (vol. lxii. p. 571), and, as pointed out on that occasion, the first instalment dealt with the geology, macro-lepidoptera, and the molluscs of the neighbourhood. As might be gathered from the titles of the sections into which the present two volumes are divided, the completed account of Church Stretton contains all that a visitor or resident is likely to want to know. Moreover, as the volumes contain the results of local scientific research and observation by competent workers, they may be used with confidence as a guide to the natural history and archæology of the district.

In the introduction to the catalogue of the birds met with in the district of Church Stretton, Mr. Paddock directs attention to the fact that owing to the persistent persecution by game preservers, some of the larger Raptores, which formerly bred there, do so no longer, and that the smaller species are, from the same cause, rapidly diminishing in number. A similar fate has befallen some members of the Corvidæ, though to a lesser degree.

Mr. Benson's catalogue of the phanerogams of Church Stretton is conveniently arranged and exhaustive in its character. Owing to the ill-health of the compiler, this list was revised by Mr. Hamilton, who deals also with the mosses of the neighbourhood.

Fundamentals of Child Study. By Edwin A. Kirkpatrick, B.S., M.Ph. Pp. xxi+384. (New York: The Macmillan Company; London: Macmillan and Co., Ltd.) Price 5*s.* net.

"This book," we are told, "is an attempt to present, in an organised form, an outline of the new science of child-study for investigators, students, teachers, and

parents. . . . It was the original intention," of the author, "to summarise all the principal child-study investigations that have been made." But this plan was evidently abandoned at a very early stage, and we have instead the present popularly written volume, which we can heartily recommend both to teachers and parents. Its style is pleasing, and its matter fairly correct, embodying the experience of fourteen years' study and teaching in the subject. Were the contents as widely read as they deserve to be, the immense importance of child-study, as a basis for methodical teaching and rational education, would be more generally realised.

The greater part of the book is devoted to the development of instincts—a word used in an extended sense by the author to embrace the phenomena of imitation, curiosity, migration, and even æsthetics, morality, and expression. These nine chapters, together with those on heredity, individuality, and on the development of the intellect, are all admirably written, containing excellent food for the parent's reflection and stimulating the interest of the teacher in her work. It seems strange that the subject of fatigue should be relegated to the chapter entitled "Abnormalities." This latter contains some useful hints on the mental and physical defects of children, but the accompanying pathological and anatomical remarks are in several instances inaccurate and misleading. C. S. M.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Residual Affinity.

THERE appears to be a tendency among chemists to abandon their own doctrine of definite valency, and to recognise an indeterminate and fluctuating number of links connecting atoms with each other.

The electron theory of the physicist, which assigns one indivisible unit of charge to a monad, two to a dyad, &c., has therefore encountered some opposition, inasmuch as it seems to tend to harden the old doctrine of "bonds" whereby atoms were supposed to be linked only in a simple definite and numerical way, no fraction of a bond being contemplated.

Assuming this rough statement to represent something like historical truth, I have a few remarks to make on the subject.

First, the possession by an atom of a definite charge, numerically specifiable as a simple multiple of an indivisible unit, must be accepted as a physical fact.

Second, this fact corresponds with those other facts which originally led chemists to assert, for instance, that nitrogen was a triad or pentad, carbon a tetrad, &c.—a position which it would seem absurd to abandon. (Incidentally it may be noted that a monad must be either electro-positive or electro-negative, but that a tetrad need not be either, since its pairs of charges may be opposite in sign.)

Third, there is nothing in these doctrines inconsistent with the existence of fractions of a bond and any required amount of "residual affinity."

It is this last thesis that I wish briefly to develop. Indeed, in 1902, in a paper on electrons published in the *Journal* of the Institution of Electrical Engineers, vol. xxxii., p. 103, I showed how it was possible to regard ordinary mechanical cohesion on the electric theory; and likewise that it was easy to regard molecular combination from the same point of view.

In a short conversation with Prof. Armstrong, at the Mansion House recently, I realised more clearly than before where the imaginary difficulty now lies.

It has been an occasional habit with physicists when speaking of lines of force to think of a single line of attraction or elastic thread joining each negative electron to its corresponding positive charge; each unit charge, in fact, being regarded as the cut end of a line of force and nothing else. But so far as I know it has never been considered that these lines of force so interpreted were physical realities, and that one and only one line really appertained to each unit charge; though in his recent remarkable book reviewed in these columns on May 26, p. 73, Prof. J. J. Thomson goes near to assigning so great a physical reality to the lines of force as would make the number issuing from any charge a commensurable number; that is to say he begins hypothetically to regard each line of force as a discrete physical entity. But even so there is no evidence that each unit of charge ought to have assigned to it one solitary line of force, it might have a great number; though it is true that on that view it becomes a definite question how many lines of force a unit charge possesses, whereas on the ordinary vaguer view of a centre of force the influence of which is felt in all directions, any specification of number of lines is either meaningless or a mere question of convenience of measurement, like the number of miles in the circumference of the earth, or the number of cubic feet in a room: a number which is necessarily and always incommensurable.

On any view electrons are supposed to repel and to be attracted with a force varying as the inverse square of the distance, and this is only consistent with a very large number of lines of force radiating from each and starting out in every direction equally.

When opposite charges have paired off in solitude, every one of these lines start from one and terminate on the other constituent of the pair, and the bundle or field of lines constitutes a full chemical "bond"; but bring other charges or other pairs into the neighbourhood, and a few threads or feelers are at once available for partial adhesion in cross directions also, the quantitative distribution of the force being easily calculable from geometrical data.

Briefly, the charge is indivisible, it is an atomic unit (up to our present knowledge); but the lines of force emanating from it are not indivisible or unified at all. The bulk of them may be occupied with straightforward chemical affinity while a few strands are operating elsewhere; and the subdivision of force may go on to any extent, giving rise to molecular combination and linking molecules into complex aggregates, so that a quite gradual change of valency is conceivably possible, the number of wandering lines being sometimes equal to, or even greater than, the number of faithful lines—though this would usually represent an unstable condition not likely to persist.

I state the position in order that physicists who see reason to disagree with it may intervene in good time and prevent any premature acceptance of a harmonising interpretation by chemists; because so long as there is any real outstanding difficulty it is clearly best for the progress of science that diverse views should continue.

OLIVER LODGE.

On a Dynamical System illustrating Spectrum Lines.

I DESIRE to express to Prof. Nagaoka my regret at my misinterpretation of his letter to NATURE of February 25, which was due simply to my failure to find any mention there of the larger system of which he speaks. No doubt his ring is quasi-stable if the central positive charge is large enough; but is it allowable to leave out of account the rest of the system? Waiving this objection, I would point out that there are upper limits to the central charge which cannot be exceeded without making the whole system positive, or the velocity of the ring greater than that of light. It may very well be that either limit is too low to allow a stable system to be reached; the discussion of this point must be reserved for another time.

G. A. SCHOTT.

Physical Laboratory, University College, Aberystwyth.

A Correction.

IN my letter to NATURE of June 16 (p. 151) concerning the source of radio-active energy, I should of course have halved the expressions given for the electrostatic energy of an isolated electron, and for energy set free by annihilation of matter. C. V. BURTON.

Cambridge, June 18.

A WORLD-WIDE BAROMETRIC SEE-SAW.

IN the year 1902, an account was given in this Journal (vol. lxvi. p. 248) of a short period atmospheric barometric variation which appeared to be closely related to the changes in the percentage frequency of prominences as observed year by year on the limb of the sun. In a later article, which appeared in the following year (vol. lxvii. p. 224), it was shown that this barometric variation consisted really of a great see-saw between two nearly antipodal parts of the earth, the one region about India and its neighbourhood behaving in an inverse way to that of South America and the southern parts of the United States. A further study of these pressure changes has recently been communicated by Sir Norman Lockyer and the writer to the Royal Society, the object being to trace the behaviour of these variations in as many regions of the earth's surface for which observations covering a sufficient period of time are available.

For this, so to speak, classification of pressure variation types, the system adopted was to take the pressure variations over India and Cordoba as the chief types of each region, denoting those of the former by the symbol (+), and those of the latter by (−). The pressure curve of any other place was then taken and compared with each. If, for example, it was found that the curve extending over several years exhibited an excess pressure at those epochs when the Indian pressure curve was in excess, then it was classified as being similar to the Indian type and represented by a (+). If it was seen that although it was more like the Indian curve than that of Cordoba, but yet not quite the exact counterpart of India, then it was denoted by (+ ?). In a similar way pressure curves like Cordoba were classified as (−), and those more like Cordoba than India as (− ?).

In some regions the pressure variation curves were distinctly a mixture of both the Indian and Cordoba types, and it was difficult to classify them satisfactorily by the above method. The symbol adopted for these cases was (± ?). Again, there were further some curves, but very few in number, in which even this mixed type of symbol was not sufficient to exhibit the relationship of their variations to the other curves, so a special symbol (?) denoting ambiguity was used.

It may here be mentioned that the pressure curves here utilised for discussion were not always formed from the values obtained by plotting the annual means, but from the means of the groups of consecutive months in which the pressure was above or below the yearly mean value. Such a division of the year can be accurately determined for places which have a regular and pronounced annual pressure variation, such as India, and where the yearly barometric range is of far greater magnitude than any other aperiodic fluctuation. In those regions where the mean yearly curve is more misleading than otherwise, such as the case of the British Isles, the divisions according to the two seasons included in the two groups of months, April to September and October to March, were adopted.

In examining the curves for the similarity or dissimilarity of the pressure changes, it was found that the special types were apparent sometimes in the yearly curves, sometimes in those for one or other of the high or low pressure groups of months, or sometimes in both of these. It did not, however, appear to follow that, because the type was distinguishable in the yearly curves, it was necessarily apparent in both the curves of the high and low pressure months.

On the accompanying map of the world are marked the types of pressure variations in each region included in this barometric survey.

Although the above classification gives a very fair idea on the whole of the types of pressure variations from one region to another, minor peculiarities have been met with which have tended to add a certain amount of difficulty. These remarks apply principally to places in the more northern latitudes. Thus, for instance, Greenland and Iceland have been classified as of the (+ ?) type, the British Isles, Germany, and Spain of the (± ?) type, and the Azores of the (− ?) type.

While the western portion of Europe is of the (± ?) type, the eastern portion gradually assumes the (− ?) type, and this region extends not only probably to Norway and Sweden, but right across European and Asiatic Russia. The European Russian type of curve has an undoubted similarity to those of more western Europe, but there are variations which indicate that the type is more like that of Cordoba than India.

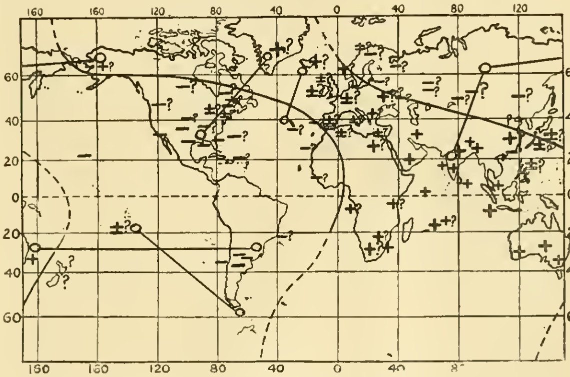

FIG. 1.—Showing the distribution of the different types of pressure variation. The two main regions are roughly separated by the neutral lines. Previously known "see-saws" are shown by the short continuous straight lines connecting the two regions marked with small circles.

Again, another region in which rather mixed types of pressures are met with is that of eastern and north-eastern Canada. Curiously enough, Prince Edward Island and Sydney (Nova Scotia) correspond very closely to the (−) type, if allowance be made for the differences about the year 1877. The inverted curve for the latter with the Adelaide (Australia) pressure curve for comparison is shown in Fig. 2.

In addition to illustrating this reversal between Adelaide (+) and Sydney (Nova Scotia) (− ?), this figure shows also, to serve as examples, curves for two other sets of reverse pressure conditions. Thus, Bombay (+) is compared with the Cordoba (−) pressure curve (inverted), and is an example of the adopted types of pressure variation. Iceland is compared with that of the Azores (inverted), and shows the reverse conditions that prevail between a (+ ?) type and a (− ?) type.

A fact to which attention was very often directed

in attempting to classify the pressure curves was that some curves, after following very closely for many years the Cordoba (−) or Indian (+) type of pressure, as the case may be, would revert back to the opposite type for a period of years. Thus, to take the case of one station alone, namely, Sydney (Nova Scotia), as an instance, the pressure curve follows very closely that of India from 1874–1882, after which, up to 1890, it has a very close resemblance to the Cordoba type. The behaviour of this Sydney (Nova Scotia) pressure curve can be compared with the Adelaide (Australia) curve in Fig. 2, but it must be noticed that the former has here been *inverted*.

The accompanying map (Fig. 1) shows the result of an attempt to indicate the position of a neutral line to illustrate approximately the mean lines of separation of these two chief pressure types, although it

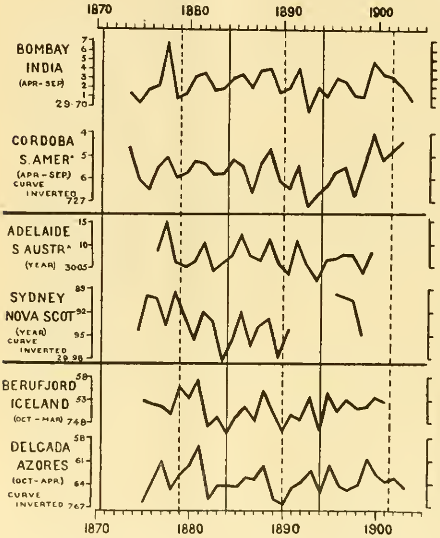

FIG 2.—Showing the two main types of pressure variation as illustrated by Bombay (+), Cordoba (−), and the barometric relationships between Adelaide and Sydney (Nova Scotia) and between Iceland and the Azores.

must be remembered that this line is liable to a probable small oscillation about its mean position.

So far as can at present be determined, one line commencing to the west of Alaska, separating this region from Siberia, passes easterly along about the 60° parallel of latitude, and runs in a south-easterly direction between south-west Greenland and north-east Canada. It then crosses the North Atlantic, passing to the north of the Azores, and skirts the south-western portion of Portugal. It then strikes down towards the Equator, cutting north-west Africa, so far as can be judged from the scant pressure values available, through the middle of the Sahara. It leaves Africa near the Gold Coast, and passes into the South Atlantic, where it cannot be traced further owing to lack of observations in this southern ocean.

The other boundary or neutral line passes to the north-east of Greenland and north of Iceland, crosses the southern portion of Norway and Sweden, and traverses southern European Russia. It then takes a course somewhat more easterly, skirting the northern part of the Caspian Sea and Turkestan, passes between Tibet and Mongolia, and through China. It then leaves the continent a little to the south of the Yellow Sea, and passes into the North Pacific Ocean. Here its path cannot be traced, but it evidently passes well to the east of the Philippine Islands, and Solomon Islands, takes a new south-westerly course, skirting the eastern side of Australia and passing between Tasmania and New Zealand. Its track is then again lost in the southern Pacific Ocean.

Although too much weight must not at present be given to the positions of these neutral lines throughout their whole length, it is interesting to note that they are fairly symmetrical to one another, although no attempt has been made to make them so. Both lines apparently cross the equator at about antipodal points, and both appear to have a similar trend in northern and southern latitudes.

The result of this survey seems to indicate clearly that there exists a general law relating to the pressure changes which occur simultaneously in these two extensive regions of the globe, separated and defined more or less by a neutral line, this latter forming a fulcrum about which see-saws of pressure from one region to another take place.

Special cases of such reverse pressure variations have previously been noticed, chief among which are those detected by Blandford, Hildebrandsson and Hann.

To illustrate these cases in relation to the present work, there have been drawn on the map (Fig. 1) small circles connected by lines to show their relation to the neutral line. A single glance is sufficient to see that in all cases except one the see-saws occur in places lying on opposite sides of the neutral line.

These results thus agree well in the main with the present distribution of the regions which have been examined.

Quite recently Prof. Bigelow, working on the same lines as those indicated in the present research, published a map of the world on which he has indicated the distribution of the pressure types according as they follow the Indian (or direct type as he calls it) or the Cordoba (indirect) pressure variations. In most of the main features, however, his map suggests a somewhat similar distribution of these pressure types to that given here. Thus, he finds that "the region around the Indian Ocean gives direct synchronism, South America and North America give inverse synchronism, while Europe and Siberia give an indifferent type. Greenland and Iceland seem to have direct type like the Indian Ocean. . . . The eastern hemisphere tends to direct synchronism, except in Europe and Russia where the indifferent type prevails, and the western hemisphere to the inverse type."

It may be mentioned in conclusion that regions which are the reverse of one another as regards these secular pressure variations should very probably experience opposite kinds of abnormal weather, while those over which the same type of pressure variation exists should have weather of an abnormal but similar nature. The intimate connection between pressure and rainfall, allowing for the local conditions as regards situation for the latter, suggests that the variation of rainfall should be closely studied in relation to this barometric surge, and it is in this way that progress may be looked for with regard to monsoon and other seasonal forecasts.

WILLIAM J. S. LOCKYER

ENGLISH FIELD-ANTHROPOLOGY.[1]

THE first organised mission sent out from this country for purely anthropological research was the outcome of Dr. Haddon's visit to Torres Straits in 1888, when he began to collect materials for a study of the natives. Ten years later, with the assistance of a fully-equipped expedition, he was able to complete the work. The reports will occupy six volumes, of which this is the first to be completed; two parts of volume ii. (Physiology and Psychology) have already appeared.

These savages constitute the ethnological frontier between Australia and New Guinea, but are distinctly Papuan. They have been in contact with white pearl-shellers and missionaries for about thirty years, and most of them are now Christianised. Though they are not a people of striking idiosyncrasy, such as the Arunta of Central Australia, and do not add to the romance of ethnology, yet this careful study of them has enriched science with several unique facts and many variations from type which will have considerable influence upon theory.

The account of the social organisation is based upon carefully revised genealogies, compiled by Dr. Rivers, which form a register of births, marriages and deaths, extending back for a hundred years. The method is an excellent one. The native system of kinship is the classificatory, with three non-essential features, which are developed in a remarkable way. The first of these is the practice of exchanging names, which seems to have been almost as common as, say, our custom of exchanging cards. The task of the genealogist was thus rendered very laborious. Secondly, the number of reciprocal terms is unprecedentedly large. Thus the term *tukoiab* denotes the relationship of brother to brother and sister to sister; it is also used and here the classificatory system appears—of all men of the same generation in the father's clan, the mother's clan, and the father's mother's clan, also of the sons of a brother and those of a sister, and of the sons of two sisters. Brothers' wives, however, are not called "wives" of *ego*; nor is there any trace of group-marriage. Polygamy was once frequent, but polyandry is unknown. The terms of relationship are also used as terms of address. In the third place we have what is perhaps the best example extant of the regulation of social duties and privileges by kinship. The division both of labour and of rights is thus harmoniously arranged. An apparently unique instance is the power of stopping fights, belonging especially to the relationship of *wadwam* (the reciprocal term for maternal uncle and nephew).

Totemism is very fully developed, both in its social and religious aspects, and has important peculiarities. Besides the principal totem a clan possesses a subsidiary one. Two important totems are crescent-shaped ornaments of tortoise-shell, with no reference to any animal or plant; they are merely decorative relics

FIG. 1.—Performer at the Saw-fish Dance, Waiben.

from the wardrobe of the hero Kwoiam, a warrior whose exploits form a considerable saga and who is more or less definitely apotheosised. These relics resemble in the powers attached to them the *churinga* of the Central Australians. But Kwoiam himself is a totem! Magical ceremonies are performed, as in Australia, to increase the supply of the totem animals as well as of the crops. An interesting feature of totemic society is the way in which the clan members try to live up to the character of their totems. The

[1] "Reports of the Cambridge Anthropological Expedition to Torres Straits. Vol. v. Sociology, Magic and Religion of the Western Islanders." Edited by A. C. Haddon, Sc.D., F.R.S., Fellow of Christ's College, Lecturer on Ethnology in the University of Cambridge. Pp. xii+378; plates xxii. (Cambridge: At the University Press, 1904.) Price 25s. net.

Cassowary men, for instance, are pugnacious, long-legged, and good runners.

Though marriage is strictly forbidden within the totem clan, its regulation belongs to kinship rather than to totemism. The phratry system, so common in Australia, seems to have formerly existed. A man sometimes lives with his wife's people, a case apparently due to circumstances which have no connection with maternal descent. The custom of the levirate is known, but it is not obligatory, and there is nothing to show it to be a survival of polyandry. It is wrong to marry an old woman. The eldest daughter is always married first. Young men rub their bodies with "sweetheart medicine" to attract the notice of the girls. It is the universal custom for the women to propose to the men.

The heads of dead persons are cured, painted and kept by the nearest relatives. It is to be noted that no worship is paid to them. Ancestor worship is unknown; the custom in question is solely due to affection. One of their funeral customs is a remarkable parallel to the ancient Roman practice; persons carefully "got up" to represent dead relatives dance at the burial.

Very interesting features are presented by the customs which have to do with property. There is no group or clan ownership of land; every inch of ground is owned by some individual. A man's property is divided at his death among his children. In default of male issue, a daughter may inherit. They have a system of leasing their gardens. If a man wants to buy a canoe he can pay by instalments with immediate possession, the *Times'* scheme being here anticipated.

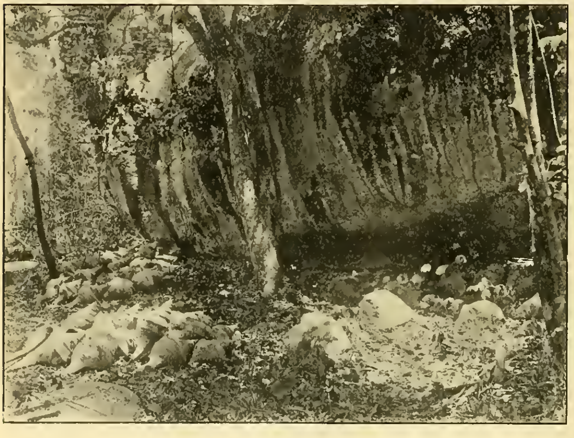

FIG. 2.—The Cave of Augudalkula in the Sacred Island of Pulu.

The account of the native religion gives an impression of incomplete study. We are told that there is no supernatural sanction for morality; even the totems are not really worshipped. We hear incidentally that the natives pray to their "heroes." An analysis of their habits of prayer would have been instructive. More information about the chief hero, Kwoiam, would have been welcome. A folk-tale speaks of the first created man: is this idea borrowed from missionaries? The concluding sentence of the volume is, "unless the above-mentioned heroes be regarded as gods, I think it can be definitely stated that the western islanders had no deities, and certainly they had no conception of a Supreme God."

We have only mentioned a few of the many facts which will assist in throwing light on old problems. That so much was done in so short a time speaks well for the energy of the expedition. But could not the hundred odd pages of folk-tales, fully reported, have been reduced? A précis of such seems adequate.

The volume is a fine monument of English anthropology, and reflects great credit on the enterprise and devotion of Dr. Haddon and his colleagues. It is by such work as this that the "science of man" is justified.

ERNEST CRAWLEY.

PROGRESS IN WIRELESS TELEGRAPHY.

IT is eighteen months or more since Mr. Marconi succeeded in establishing wireless communication across the Atlantic. On that occasion a few congratulatory messages were exchanged, a great deal was written on the subject in the Press, and the more timorous of cable shareholders were reported to be much troubled. A little later the attempt was made to demonstrate that this achievement was not merely a firework display, but was capable of direct commercial application; the Marconi Co. entered into a contract to supply the *Times* with news from America by wireless telegraphy, and for a day or so there appeared items of news in that paper under the heading "By Marconigraph." But after a few messages something went wrong, and the public were given to understand that a piece of auxiliary machinery had broken down. It is to be presumed that this piece of machinery has at length been repaired, for Mr. Marconi has once again come very much to the front with long-distance transmission work. The announcement, which we published last week, that he had been successful in maintaining a supply of news to the *Campania* on her voyage across the Atlantic with a regularity sufficient to allow of the publication of a daily paper on board that vessel affords evidence that he is still steadily pushing forward the practical development of wireless telegraphy. We have repeatedly urged in these columns that the real work of wireless telegraphy lay in communication with ships, and it is therefore a greater pleasure to record this latest development than it would be to announce the reopening of Trans-atlantic communication.

The experiments on board the *Campania* appear to have been thoroughly successful in all respects. Not only was the vessel never out of touch either with one or other of the three large power installations, but she was also for a considerable period in touch with both sides. It seems, however, that the communication was only one sided; this is, of course, only what was to be expected, but it is to be hoped that Mr. Marconi's efforts will be directed to making it reciprocal, and that before long we shall hear the announcement of this further success. It is stated that the other ships of the Cunard line are to be installed with apparatus similar to that on the *Campania*, and that a regular news service will be established to all of them. There can be no question but that this will tend very greatly to enliven the voyage across the Atlantic, and that in many other respects it will be of great practical utility.

In other directions wireless telegraphy is showing that it has won the right to consideration as a thoroughly practical means of communication. The extract from a letter from the "wireless" correspondent of the *Times* in the Far East which was printed in last week's NATURE shows to how great an extent it is being used in the Russo-Japanese war. The letter also shows that, whatever may be said to the contrary, syntonisation in the true sense is still a problem awaiting solution. The most that can be done at present seems to amount to this: a receiving station can be syntonised sufficiently well to enable it to pick up messages from a particular transmitting station in preference to, or with greater ease than, those from any other, and thus it may be enabled to work over greater ranges. It does not, however, seem in the least possible so to tune the transmitter that interception of messages is impossible, nor does it seem likely that this will ever be accomplished until experimenters have succeeded in producing continuous trains of undamped oscillations, a direction in which many are working. It is noteworthy that Dr. de Forest recently expressed the opinion that without this syntonisation is only partially possible; in this limited sense we believe all systems are making use of the principle with more or less success. The system designed by Dr. de Forest appears from many accounts to be the most efficient of those at work at the seat of war, as it has already been one of the most successful of those tried in America. The lengthy wireless messages transmitted with marked regularity in trying circumstances from the *Haimun* to the *Times* afford evidence of this, and it is noteworthy also that a speed of about thirty words a minute seems to be easily attained, which is a high speed for wireless telegraphy. The comparisons which the *Times* correspondent makes between the working of his system and that on the British warships at Wei-hai-wei, though much to the detriment of the latter, are hardly fair to the Marconi system, as the naval installations are not of the latest date.

As to the prospect of attaining thorough syntonisation, it is to be noted that Dr. de Forest is working on the lines of producing continuous oscillations on the principle of Duddell's singing arc, a method which, we pointed out in NATURE (vol. lxviii. p. 248), seemed the most promising. Others, we believe, are also working on the same lines. It is noteworthy also that much progress has been made on the scientific side, and that we are in a better position now to make quantitative measurements of the energy transmitted and received. In this connection also Mr. Duddell has contributed towards our advance; he recently exhibited before the Physical Society an instrument (which we hope to describe on another occasion) which gave considerable deflections with the currents received in the aërial wires. As this affords the first means we have of accurately measuring these currents, it may prove of great value in the development of the science.

MAURICE SOLOMON.

REPORT OF THE METEOROLOGICAL GRANT COMMITTEE.

IN December, 1902, a committee was appointed by the Treasury "to inquire and report as to the administration by the Meteorological Council of the existing parliamentary grant, and as to whether any changes in its apportionment are desirable in the interest of meteorological science, and to make any further recommendations which may occur to them with a view to increasing the utility of that grant." The committee was composed of Sir Herbert E. Maxwell, Bart., M.P. (chairman), Mr. J. A. Dewar, M.P., Sir W. de W. Abney, K.C.B., F.R.S., Sir F. Hopwood, K.C.B., C.M.G., Board of Trade, Sir T. H. Elliott, K.C.B., Board of Agriculture, Mr. T. L. Heath, Treasury, Dr. R. T. Glazebrook, F.R.S., and Prof. Joseph Larmor, F.R.S.

The report of the committee has just been published as a Blue-book (Cd. 2123, price $2\frac{1}{2}d.$), and a summary of some of the points of scientific interest in it is subjoined.

SCIENTIFIC RESEARCH.

The committee of 1877 recommended that "the council should be at liberty to appropriate a part of their annual grant to the purposes of any special researches which they may think important, and in such cases it should rest with them to select the investigators and fix the remuneration."

The council, as might be expected of a body appointed by, and reporting annually to, the Royal Society, has never lost sight of this part of its functions; but the expansion of the routine work of the office, including therein the receipt, discussion and reduction of observations, the preparation and issue of forecasts and warnings, the supply of instruments and the annual inspection of observatories, &c., has absorbed nearly the whole of the grant, leaving a comparatively trifling sum—700*l.* to 800*l.*—to be devoted to meteorological research. The council has made a strong representation that, for the effective performance of this part of its duties, the staff requires strengthening by the addition of "a few assistants specially qualified by a knowledge of mathematics and physics for undertaking the investigation of such questions as are contemplated." The additional annual cost of three such assistants, with the incidental expenses, was estimated at 2250*l.* It appears from the evidence that it would be desirable for the council to have access to a meteorological laboratory properly equipped, which would serve as one of the first-order observing stations.

We believe that the time has arrived when one of two alternatives must be taken, viz. either to provide the Meteorological Office with the additional funds necessary for the effective prosecution of independent and cooperative research, or practically to confine the functions of the Meteorological Office to the ordinary routine work. In this latter case it would be necessary to rely upon members of the council who are appointed by the Royal Society to keep abreast of the advance in meteorology which may be achieved by British and foreign scientific societies and by the Governments of foreign countries independently of the office.

We do not believe that a middle course can be pursued with any advantage. The present grant is little more than enough to maintain the office, the five observatories depending thereon, and the library, and to provide for the superannuation of the staff. It would be better to circumscribe the operations of the council to routine than to expect them to undertake investigations for which they have not adequate means.

An example of the difficulty arising under present conditions may be cited in the invitation forwarded by the Foreign Office to the council in 1902 to join in an international scheme for investigating the upper atmosphere by means of kites and balloons. The invitation had to be declined for want of the requisite 500*l.* a year.

It is clear that, from the first, it was intended that the directors of the Meteorological Office should be chosen with a view to their capacity for directing experiment and research; otherwise their appointment would not have been committed to the Royal Society. On the other hand, we perceive strong objections to granting money for scientific research in meteorology, except on the direct responsibility of a Minister of the Crown. This brings us back to the repeated recommendation of the Royal Society that the Meteorological Office should form part of one of the Government departments—a recommendation which we have included among those now submitted to your lordships.

It appears that the present constitution of the Meteorological Office was never regarded by the Royal Society as a permanent one, but as "a temporary measure till some other organisation should be carried out." We regard this as a favourable opportunity for placing the Meteorological Office upon a permanent footing.

RECOMMENDATIONS.

We are of opinion that the registration of the Meteorological Office as a company under the Joint Stock Companies' Acts should be cancelled, that the company should be wound up, and the office reconstituted as a department under the control of the Board of Agriculture and Fisheries.

The necessity for a council of seven having thus been got rid of, we recommend that the office be placed under the control of a man of science as director of meteorology, appointed after consultation with the Royal Society, but responsible to the Board of Agriculture and Fisheries, and making his annual report to that department. We recommend also the appointment of an advisory board, consisting of the hydrographer to the Admiralty, a representative of the Board of Trade, and one of the Board of Agriculture and Fisheries, and two members nominated by the Royal Society. The functions of the advisory board should be consultative only, the director being responsible to the Board of Agriculture and Fisheries for administration.

We recommend also that a second officer be appointed to act as scientific assistant to the director, to assist him in the general management of the office and in the discussion of such scientific problems as may arise.

The mean annual cost of this arrangement, as compared with that for the present council, we estimate thus:—

Present Arrangement		*Proposed Arrangement*	
Council	£850	Director £800 rising to	£1000
Secretary	625	Scientific Assistant ...	450
	£1475	Mean	£1350

The fixed parliamentary grant of 15,300*l*. should be transferred to the vote for the Board of Agriculture and Fisheries.

Under such an arrangement the anomaly would cease of what is practically a department of the public service, though nominally a joint stock company, paying for postal and telegraph services money out of its fixed income. The charge for these services would not appear in the estimate, though undoubtedly the revenue would be the loser by the amount now repaid out of the parliamentary grant. The director of meteorology would not then feel, as the council now does, that the more complete and rapid the distribution of forecasts and warnings is made, the less money remains for scientific research and for overtaking arrears in the statistical work of the department.

Further, we judge it important that the Post Office should make arrangements at the twenty-seven reporting stations in the United Kingdom for the transmission of daily telegraphic reports one hour earlier than the present one of 8.15 to 8.30 a.m., and that storm warnings should, if practicable, have priority over all private messages at all hours.

We would direct attention to the expediency of testing the efficacy of wireless telegraphy in providing advance news of weather in the Atlantic. Such news would incalculably strengthen the forecast and warning service, and might, we believe, be obtained regularly over an experimental period by cooperation either with the Admiralty, the ocean steamship companies, or both. We would urge that no unnecessary delay should take place in organising this experiment.

We recommend that in future the cost of instruments supplied to His Majesty's ships be borne upon the Navy votes, except where such instruments are intended for use in research or observation specially called for by the director of meteorology.

We consider that the premises now rented by the council are neither suitable in character nor adequate in space for the present requirements of the office, and that others should be provided wherein the staff might perform their duties under more favourable hygienic conditions, and necessary accommodation for the rapidly growing library might be secured.

We recommend that the staff employed in the library, the statistical branch and observatory branch, should be augmented. The steps necessary to give effect to this and the preceding recommendation can best be determined when the future of the office has been decided upon.

We have carefully considered the effect of our recommendations upon the apportionment of the present grant of 15,300*l*.

Our recommendations would involve a net increase of 449*l*. Another effect would be to reduce the Post Office revenue by the sum of about 2000*l*., and to transfer to Navy votes, for instruments supplied to the Royal Navy, about 500*l*.

In default of an increase to the grant, the small increased expenditure which we have recommended would have either to be postponed or to be met from economies on other branches of the work of the office.

We have not included in the figures above given any increase in the average amount of the grant allocated to scientific research, nor have we found means of providing for increased telegraph expenditure which the adoption of the recommendations as to the transmission of earlier daily telegraphic reports, and of storm warnings, will very probably entail on the Post Office.

The evidence before us has shown conclusively the importance of further scientific research, for which we trust that funds may be forthcoming in the near future.

In minority reports Sir Herbert Maxwell and Sir William Abney express disagreement with that part of the report which deals with the action of the Meteorological Council in deciding to discontinue the annual payment to Fort William Observatory, involving the abandonment of the observatory on Ben Nevis.

Mr. Dewar objects to the action taken by the council in connection with superannuation; and Sir Francis Hopwood and Mr. T. L. Heath are unable to concur in the recommendations made by a majority of the committee (*a*) in so far as they would necessarily involve an increase in the annual grant, and (*b*) in so far as they relate to the transfer of this grant from the vote for scientific investigations, &c., to that of the Board of Agriculture and Fisheries.

NOTES.

THE following announcement of a munificent gift for scientific research appeared in Monday's *Times*:—Mrs. Percy Sladen, of Northbrook Park, Devonshire, in the desire to perpetuate the memory of her late husband, Mr. W. P. Sladen, sometime secretary and vice-president of the Linnean Society, has undertaken to devote the sum of 20,000*l*. to the promotion of scientific research, particularly in the subjects in which he was chiefly interested. She proposes to assign this sum under the name of the Percy Sladen memorial fund to certain trustees, in the first place of her own appointment, who are directed to employ the income arising therefrom, in their uncontrolled discretion, to "any research or investigation in natural science, and more especially in the sciences of zoology, geology, and anthropology." They are also empowered, if they think fit, to accumulate the income for the purpose of fitting out, or assisting to fit out, any expedition designed to further such research. The following gentlemen, whom Mrs. Sladen has requested to be the first trustees, have consented to serve:—her brother, Dr. Tempest Anderson, of York; Mr. Bailey Saunders, Mr. Henry Bury, Dr. Henry Woodward, F.R.S., Prof. Howes, F.R.S., and Prof. Herdman, F.R.S. On the occurrence of any vacancy among these trustees, Mrs. Sladen reserves to herself the right to nominate their successors; but by the deed of endowment it is provided that eventually five trustees shall be severally nominated for a period of five years each by the following bodies in rotation, so far as they may have signified their acceptance of the power of appointment:—the Royal Society, the Linnean Society, the trustees of the British Museum, and the Universities of Oxford and Cambridge.

As a result of a petition in 1902 from the Johannesburg branch of the South African Association for the Advancement of Science to the Governor of the colony, a Govern-

ment observatory is now in course of erection near Johannesburg. Mr. Theodore Reunert, as honorary secretary of the South African Association, has been specially active in securing the observatory, and he is to be congratulated on the success of his efforts. His representations led to the decision to form a meteorological department as a sub-department of the Colonial Secretary's office, and Mr. R. T. A. Innes was appointed its director. The site near Johannesburg selected for the observatory is at an elevation of about 200 feet above the Bezuidenhout Valley on the south, to which it dips almost precipitously. On the north the slope is considerable, the difference in height between the summit and the northern boundary of the observatory property being about 100 feet. The summit, which includes some two acres of fairly even ground, is 180 feet higher than Johannesburg, or about 5900 feet above sea-level. The prevailing winds ensure freedom from smoke and dust. The site covers 10·6 acres, and is estimated to be worth, at the market price, 10,000*l.* at least, though the actual cost was, owing to successful negotiations, only 2500*l.* While the observatory is being built the meteorological department is lodged in the New High Court Building in Johannesburg. Arrangements have been made for the establishment of 150 observation stations at various centres of the Transvaal under volunteer observers, and from these stations observations are regularly transmitted to the director of the Government Observatory, Johannesburg.

IN addition to a number of skins of small mammals, the Hon. N. C. Rothschild has recently presented to the British Museum the entire skeleton and skin of a Nubian wild ass, obtained by himself during a sporting trip to the eastern Sudan. The skin of this wild ass (*Equus asinus nubianus*) has been set up by Rowland Ward, Ltd., and is the first entire specimen of its kind exhibited in the museum. A second specimen is, we believe, being mounted for Mr. Walter Rothschild's museum at Tring.

AN announcement of special interest was made at the meeting of the Zoological Society of London held on June 7. So long ago as 1870 the late Prof. C. Peters described, under the name of *Dinomys branicki*, a remarkable paca-like rodent of which a single example had been found some time previously wandering about the courtyard of a house in Lima. From that day until a few months ago nothing more had been heard of this strange creature, which is regarded as representing not only a genus, but likewise a family by itself. Now, however, Dr. Goeldi announces that he has specimens of this rodent living in the museum under his charge at Pará. His description of these specimens will be awaited with great interest.

AT a meeting held recently in Trinity College, Dublin, it was agreed that the great eminence of the late Provost, and his life-long connection with the university, demand a permanent commemoration in the form of some suitable memorial. A general and an executive committee have therefore been formed, and they invite the support of all graduates of Trinity College and other friends and admirers of Dr. Salmon in establishing a memorial to him. The exact form of the memorial will be decided at a meeting to be held later. In the meantime, subscriptions will be received and acknowledged by the honorary secretaries, Messrs. T. T. Gray, E. J. Gwynn, W. E. Thrift, and W. Kennedy, or the treasurers, the Right Hon. Mr. Justice Madden and the Right Hon. the Lord Justice Fitzgibbon.

A MURAL tablet erected by the Royal Institute of British Architects to the memory of the late Mr. F. C. Penrose, F.R.S., was unveiled in the crypt of St. Paul's Cathedral on Saturday last. Sir L. Alma-Tadema, who performed the ceremony, remarked that Mr. Penrose's accurate measurements revealed how far the Greeks had gone beyond the use of the straight line into comprehension of the hidden curve. He showed, for instance, that the lines of the base of the Parthenon were curved in order to appear straight, and that columns on the same plane were made different in size in order to create a more perfect and harmonious impression of uniformity. It was Mr. Penrose who directed the strengthening of the Parthenon after the earthquake of 1894. His knowledge of astronomy led him to make valuable researches concerning the orientation of ancient temples; and work of the highest importance being done to-day in Greece by a band of young excavators, who had, among other achievements, caused Crete to yield her buried treasures, was directly due to Penrose, through whom the British School of Archæology at Athens came into being.

THE death is announced of Prof. Victor de Luynes, director of the laboratory of the French Minister of Finance.

THE *Daily Chronicle* announces that Prince Albert of Monaco has taken the lead in a movement for another North Pole expedition on a plan prepared by Ensign Charles Benard, late of the French Navy. The cost of the expedition is set down at 60,000*l.*, two ships being employed.

UPON the authority of the St. Petersburg correspondent of the *Journal*, of Paris, the *Times* announces that the installation of a service of wireless telegraphy at Lake Baikal is almost complete, and will be in working order by the end of the week. It will consist of three stations, one of which will be on board the ice-breaker, which will thus be enabled to communicate with both shores during its passage across the lake.

AT the first meeting of the 1904 session of the Canterbury Philosophical Institute, held on May 4, the president, Dr. Charles Chilton, congratulated Captain Hutton on the publication of the "Index Faunæ Novæ Zealandiæ," and presented to him an album containing congratulatory addresses on the subject from the Canterbury Philosophical Institute, the Otago Institute, and from the various specialists who assisted Captain Hutton in the preparation of the "Index."

AT the seventieth annual general meeting of the Royal Statistical Society on Tuesday, June 21, Sir Francis S. Powell, Bart., M.P., was elected president for the ensuing session. It was announced that the Guy medal (silver) had been awarded to Mr. D. A. Thomas, M.P., for his paper on the growth and direction of our foreign trade in coal during the last half century, the presentation to be made in November. It was also announced that the subject of the essays for the Howard medal, which would be awarded in 1905, with 20*l.* as heretofore, was: a critical inquiry into the comparative prevalence of lunacy and other mental defects in the United Kingdom during the last fifty years

THE annual general meeting of the Palæontographical Society was held on Friday last, June 17, Dr. Henry Woodward, F.R.S., president, being in the chair. In the annual report of the council special reference was made to the activity at present prevailing among British palæontologists. The society has received more offers of monographs than it can accept for immediate publication, but it has expended more than 200*l.* of its accumulated funds in issuing an unusually large volume for 1903. Dr. Henry Woodward was re-elected president, Dr. George J. Hinde, F.R.S., was elected treasurer, and Dr. A. Smith Woodward was re-elected secretary.

At the Royal Agricultural Society's show, which was opened on Tuesday, there were in the building devoted to agricultural education and forestry a number of exhibits of interest. These came, for the most part, from the colleges where agricultural matters are taught. The Rothamsted Experiment Station sent a series of specimens of wheat and of loaves made from the flour of various samples. The results obtained, though illustrating the general experience that wheat containing much gluten yields "strong" flour that makes a big loaf, served rather to disprove the view that the quantity of nitrogenous matter present which is soluble in alcohol, or the ripeness or greenness of the corn, had any particular effect. In the bacteriological exhibit from the Midland Agricultural Institute were specimens which showed that Mr. John Golding has been able to confirm Mr. Charles Marshall's discovery (*Centralb. fur Bakteriologie*, vol. xi., April) that if in a "milk starter" an alkali-forming germ is associated with one that produces lactic acid, "ripening" of the cream takes place much more rapidly. From the same institution came a large number of hybrid potato seedlings raised by Mr. E. Miles. The agricultural section of the Essex Technical Laboratories showed some charts proving that even if the application of sulphates to the soil does not result in a larger crop, it increases its feeding value, the result being due to the larger proportion of amides which are formed. There were also specimens illustrating some new experiments showing the beneficial effects of manures upon "clover-sick" and derelict land. Very striking were the results of applying pinches of sulphate of ammonium to a lawn containing plantains; while the latter were killed, the grass and clover were affected for the better. The chief feature of the Wye College exhibits were living specimens of plants infested with fungoid and insect pests. The Agricultural Department of Cambridge, Reading College, and Harper-Adams College were also well represented, as was the Royal Agricultural Society itself. The forestry exhibition was a new feature, and in it was a representative series of specimens of timber illustrating the healing of wounds and the life-history of plants and animals injurious to trees. There were also a large number of photographs illustrating various points in forestry, together with the examples of the tools used and plots laid out with young trees.

In the Harveian Oration delivered on Tuesday at the Royal College of Physicians, Dr. Richard Caton described some results of an inquiry into the earliest records of medicine in ancient Egypt, particularly as regards the circulation of the blood and diseases of the circulation. The most interesting figure among the early physicians of Egypt was a priest of Ra, the sun god, named I-em-hotep, who lived during the third dynasty, nearly 6000 years ago, and was succeeded by a cult of priest-physicians who carried on his work of healing. Temples for the worship of I-em-hotep, which were also hospitals for the sick, arose first at Memphis, and then extended to other parts of Egypt. Here the priests not only treated the sick, but also embalmed the bodies of men and the sacred animals. In this process the heart and viscera were removed, and the priests had thus an opportunity of learning something of anatomy and of the changes produced by disease. These priest-physicians were probably the first to acquire a rudimentary knowledge of the movement of the blood. It was clear that medical science was cultivated and had advanced considerably in Egypt long before it arose in Greece. In Egypt the evidence of this fact was decisive, and in the writings of the pseudo-Apuleius it was interesting to note that Hermes told the youthful Asklepios of his predecessor, the first inventor of medicine, the Egyptian god I-em-hotep. When, in later times, Greek colonists came to Egypt, they recognised I-em-hotep as a sort of pre-existing Asklepios, and spoke of his temples as Asklepieia. The views of the circulation of the blood entertained by the Greeks were almost exactly those of their predecessors, the Egyptians; and, in view of the frequent intercourse between the two countries at that time, it was highly probable that the Greek physicians obtained their knowledge of the circulation, such as it was, from the Egyptians. The Egyptian priests seemed, in fact, to have been the first to engage in that momentous inquiry which was finally solved by Harvey, and on which the progress of medicine depended.

In the article on geodesy which appeared in Nature of June 2, referring to a contribution on the subject in the *Revue générale des Sciences*, it appears that, inadvertently, the author hardly did justice to the scientific investigations of MM. Benoit and Guillaume, the director and assistant director of the Bureau international des Poids et Mesures. The apparatus represented in Fig. 1 of our article is entirely new, and is due to the inventive faculty of those gentlemen, and not to that of M. Jäderin. That useful combination of metals known as invar is also the result of researches instituted at the Bureau International, the officers of which department may well congratulate themselves on the successful results of those investigations which they have initiated in all branches of research connected with geodesy.

The *British Journal of Photography* has just completed its fiftieth year. To mark this occasion, the editor has issued a special (jubilee) number of the journal, containing not only "the story" of the journal from its commencement to the present time, written by himself, but a series of most interesting articles by different authors on a great number of photographic topics. The *British Journal of Photography* is the outcome of the photographic energy displayed in Liverpool in the 'fifties, the first number, entitled the *Liverpool Photographic Journal*, appearing on January 14, 1854. In the "story" are given facsimiles of the title-page and the first page of this journal, and also that of the first page under the present title. Short biographical sketches of the editors and assistant editors are also included.

Dr. J. Hann recently submitted to the Vienna Academy of Sciences a work on the decrease of temperature with height up to 10 kilometres, deduced from the results of the international balloon ascents so far as they have been published. He found that the monthly means were too much influenced by the weather conditions of the days on which the ascents were made to show a tolerably trustworthy yearly range. But dealing with the *differences* of temperature for intervals of 1 kilometre, that is, with the values of the decrease of temperature with height, he was able to obtain more satisfactory and somewhat striking results. The yearly range of the differences for 1 to 3 kilometres exhibited the quickest decrease of temperature between May and June. At altitudes of 3 to 5 and 5 to 7 kilometres, the quickest decrease occurred in March and April, while at the height of 7 to 9 kilometres it occurred quite unexpectedly about the beginning of July. As first pointed out by M. Teisserenc de Bort, the decrease of temperature with height in the lower strata of air is slower in anticyclones than in cyclones, while at great heights these conditions are reversed.

Dr. Vidi, in a popular article, gives some interesting details with regard to cancer houses and districts (*Le Journal*,

Paris, May 5). One striking instance is given of a cancer district, viz. at Luckau, a small town in northern Prussia, where Behla has investigated the incidence of cancer from 1878 to 1899. The town consists of two portions, one on higher ground, which is well drained and consists of 415 houses, the other low-lying, damp, and surrounded with canals, consisting of 115 houses. In the latter, during the twenty years, seventy-five cases of cancer occurred, while in the former, nearly four times as large, only sixty-five cases occurred during the same period.

ON a previous occasion reference has been made in our columns to the investigations of Dr. C. H. Eigenmann into the structure of the eye of the blind fishes (Amblyopsidæ). A fuller and more detailed memoir by the same investigator on the eye of Amblyopsis has recently been published in *Contributions* from the Zoological Laboratory of Indiana University (No. 50). The author finds that although the foundations of the eye are normally laid, instead of developing with the aid of new material, the superstructure is completed out of that provided for the foundation, and that in the end complete disintegration takes place.

WE have received from the U.S. National Committee of Audubon Societies a batch of leaflets (published at New York) on bird protection and on the teaching of ornithology in schools, and likewise the combined report of that body and the A.O.U. Committee on the Protection of North American Birds for 1903, extracted from the *Auk* for January. The leaflets contain excellent portraits and descriptions of some of the most beneficial of North American birds, one being specially devoted to the snowy heron, or egret, and to the oft-told tale of the iniquity of wearing "aigrettes" and "ospreys." The report, which is illustrated with reproductions from photographs of bird life in protected localities, emphasises the satisfactory results which have accrued from the special protection extended to gulls and terns by means of the Thayer fund.

IN his usual interesting style, Mr. E. T. Seton, in the June number of the *Century Magazine*, gives an account of the labours of the little burrowing rodents commonly known as pocket-gophers, and their effect on the soil. According to the author's personal observations, true earth-worms are unknown in Manitoba, and, indeed, in all that part of North America lying to the south of the Saskatchewan and west of the Mississippi, with the exception of a narrow humid belt along the Pacific coast; and it would seem that the work performed by those annelids in other parts of the world is accomplished in western North America by pocket-gophers. In Manitoba the surface soil consists of a layer of black humus from a foot to two feet in thickness, and there can be little doubt that this layer, which is not a solid bed of decayed vegetation, has been thoroughly mixed up with the subjacent loam by the action of burrowing rodents, foremost among which are pocket-gophers.

APPENDIX iii. to the Kew *Bulletin* has been received, which contains a list of the new garden plants of the year 1903.

IN the *Journal* of the Asiatic Society of Bengal, No. 4, vol. lxxii., Sir George King, F.R.S., in conjunction with Mr. J. S. Gamble, F.R.S., continues the "Materials for a Flora of the Malay Peninsula." The contribution contains the order Caprifoliaceæ (three species of Viburnum), and those species of the Rubiaceæ which possess numerous ovules in each cell of the ovary. This tropical order is well represented, and the authors have added a number of new species, including fourteen for Argostemma, nine for Randia, and four for the morphologically interesting genus Mussænda.

THE subject of nuclear fusion in vegetative cells is treated in three papers by Dr. Nemec which have appeared in the *Sitzungsberichte* of the Royal Scientific Society of Bohemia (1902, 1903). By the action of such irritant solutions as copper sulphate or chloral hydrate, it is possible to induce anomalous developments in the cells of the meristematic region of seedling roots whereby the formation of the cell wall consequent to cell division is suspended, and a bi-nuclear condition is established. Fusion of the two nuclei follows, and the resulting nucleus in the succeeding division shows twice the ordinary number of chromosomes. This number is maintained for a time, but eventually a reduction takes place, and the ordinary number of chromosomes appear on the spindle.

WE have received from Messrs. Armbrecht, Nelson and Co. a fine example of flexible sandstone, known also as itacolumite, from its occurrence on Itacolumi, a mountain near the town of Ouro Preto, in the State of Minas Gereas in Brazil, where it was first discovered. This variety of rock has been found in several localities in the United States, and also in India. Examples were obtained by the late General C. A. McMahon from Kaliana, a hill near Dadri, about 60 miles west of Delhi. He regarded it as a local and modified form of the quartzite of the district. Certain beds of earthy cellular quartzite are there quarried for millstones, and the stone-cutters come abruptly upon the flexible stone when engaged in quarrying. This stone occurs in irregular patches, and its flexibility appears to be due to the partial removal of the felspathic cement to which the rigidity of the mass of the adjacent rocks is due. The rock does not possess a schistose structure, and the flexibility is not due to the presence of talc or mica, the peculiar character being due to the decomposition or dissolution of portions of the matrix of the quartzite.

PROFESSIONAL paper No. 9 (forestry series) of the United States Geological Survey deals with the forest conditions in the Cascade Range Forest Reserve, and forms the sixth paper of the series. A description of the first five papers will be found in NATURE, vol. lxviii. p. 406. The Cascade Range Forest Reserve covers an area of 7254 square miles, and is the largest of all the reserves. The introduction deals with the general topographical, geological, and climatic features of the area, the classification of lands, such as forested, burned, open, &c., together with the total stand of timber, which exceeds 50,000,000,000 feet. The species are varied, although the timber consists almost entirely of conifers. The reserve is divided into thirty-seven townships, which are again subdivided into ranges. The bulk of the report deals with the classification of lands, stand of timber, species, and forest conditions in the several ranges. The value of the report is greatly enhanced by the forty-one illustrations, consisting of photographs, maps, and diagrams.

WE have received from Messrs. A. and J. Smith, of Aberdeen, a descriptive catalogue containing full particulars of Prof. Hay's apparatus devised for the investigations conducted by Dr. Leslie Mackenzie and himself for the Royal Commission on Physical Training. In addition, the list contains information of other appliances suitable for the measurement of children.

THE most recent addition to the Patent Office Library Series is the "Subject List of Works on Electricity, Magnetism, and Electro-Technics, in the Library of the

Patent Office," which costs sixpence. The list consists of two parts; first, a general alphabet of subject headings, with entries in chronological order of the works arranged under these headings, and, secondly, a key, or a summary of these headings shown in class order. The list comprises 2374 works, representing 3792 volumes.

THE series of eight lectures on "Physical Chemistry and its Applications," delivered some time ago by Prof. J. H. van 't Hoff at the invitation of the University of Chicago, has recently been translated into French by Prof. Corvisy (A. Hermann, Paris). No higher tribute to the intrinsic merit of these most readable lectures could be desired, and they will no doubt be warmly received by a large circle of French readers.

SOME noteworthy experimental results communicated by Messrs. van Calcar and Lobry de Bruyn to the current volume of the *Recueil des Travaux chimiques des Pays-Bas*, vol. xxiii. p. 218, show that considerable changes take place in the concentration of solutions under the influence of centrifugal forces. The concentration increases from the axis of rotation towards the periphery, and the changes have been accurately measured in the case of potassium iodide and cane sugar. Portions of a solution of potassium iodide of 0·2035 normal concentration, removed respectively from points near the axis of rotation and some distance away, were found to be 0·1065 normal and 0·325 normal. These portions of solution were removed after centrifuging for three hours at the rate of 2400 revolutions per minute. A saturated solution of Glauber's salt, containing 8·8 per cent. Na_2SO_4, deposited 57 grams of solid $Na_2SO_4.10H_2O$ at the periphery after being rotated for five hours, and the remaining solution was found to contain only 5·5 per cent. of sodium sulphate. It is calculated that the applied force acting on the molecules at the periphery (radius of rotation = 6 cm.) in these experiments was more than 400 times greater than gravitational force.

IN the *Revue de Metallurgie* for April, M. H. Le Chatelier re-states and explains his views on the constitution of the carbon-iron alloys. He points out the importance of classifying the constituents of heterogeneous bodies, and again directs attention to the similarity between alloys and igneous rocks. In chemical classification it is necessary to give the chief place to the conception of phases, and to regard chemical composition as of secondary importance. If chemical composition alone were used for purposes of classification, there would be no distinction, for example, between crystallised granite and fused granite, although the former contains three phases, quartz, felspar and mica, and the latter contains only one phase. Moreover, it is desirable to give names to the phases, even when they are solid solutions of variable composition. One of the great difficulties in determining the phases in the steels is that the individual crystals are generally so minute that they cannot be isolated, and their properties and chemical composition cannot be exactly determined. Nevertheless, some progress has been made in the recognition of the various phases that may occur. M. Le Chatelier believes that these phases include iron in its various allotropic forms; carbon in the form of graphite; cementite, or Fe_3C; and many solid solutions containing iron and either carbon, nickel, manganese, phosphorus, silicon, or other elements. Most of these phases have not yet received names, but the highly important carbon-iron solutions have been called troostite, martensite, and austenite. The homogeneity of these phases has been called in question, but the attempts to prove that they are heterogeneous have not yet been successful. Difficulties are occasioned by the similarity of the properties of these three solutions, and the evidence that they are distinct rests mainly on their appearance under the microscope after treatment by different reagents. It is scarcely necessary to add that these views are not shared by some students of metallography.

OUR ASTRONOMICAL COLUMN.

THE GOVERNMENT OBSERVATORY, BOMBAY.—The report of the Bombay Observatory for the year ending December 31, 1903, signed by the director, Mr. N. A. F. Moos, gives an account of the many and varied observations carried out there. The instrumental equipment is extensive and in good order, the records of failure by the automatic registering instruments being very few.

The rainfall for the year was 84·49 inches, a surplus of 9·33 inches above the average of the twenty-four years 1873–1896. The daily wind pressures and temperatures were recorded regularly, and many magnetic and seismographic observations were made daily. Routine observations with the transit instrument, to check the standard clocks, were made at regular intervals, and a very good time service was maintained at the docks and other public places. The rating and adjustment of chronometers and deck-watches for Government departments and ships, and for private ship owners, formed an important part of the year's work.

NEBULOUS AREAS OF THE SKY.—In an article published in *Popular Astronomy* (No. 6, vol. xii.), Prof. H. C. Wilson, of the Goodsell Observatory, discusses the subjective existence of the large nebulous areas of the sky as described by Sir William Herschel. He fully confirms Herschel's observations, and considers that the negative results obtained by Dr. Roberts last year must have been due to unfavourable observing conditions. Further, he shows by a reproduction of one of his own beautiful photographs of the Pleiades region, which was taken with a 6-inch Brashear star-camera, that at least one of the regions described by Dr. Roberts as containing no nebulosity is in reality filled with nebulous matter, covering as many square degrees as Herschel allotted to the whole of the nebulosities in his fifty-two regions.

Profs. Wilson and Payne intend transporting their photographic equipment to a station situated in the western Montana mountains at an altitude of about one mile, so that during July and August they may test the suitability of the atmosphere at that altitude for photographing the nebulous patches of the Milky Way, and, if possible, obtain further confirmatory photographs of Herschel's regions.

LIGHT CURVE OF δ CEPHEI.—From an exhaustive discussion of the available data concerning the magnitude variations of δ Cephei, M. Beliawsky, of St. Petersburg, has derived the following elements:—

Minimum 0 = 1840 September 24·833d. M.T. Bonn.
Period = 5·36642 days.

The period between a maximum and the succeeding minimum, according to the curve, is 1d. 11·184h., and this value is very near the mean of the values obtained by five previous workers. The light of the star varies between magnitudes 4·37 and 3·57, and M. Beliawsky gives the estimated magnitude for every 0·1 day between two succeeding minima (*Astronomische Nachrichten*, No. 3952).

POSITION OF THE AXIS OF ROTATION OF MARS.—*Bulletin* No. 9 of the Lowell Observatory gives the results of a new determination of the position of the axis of rotation of Mars, made by Mr. Lowell. The direct method was employed, the position angle of the tangent to the limb at the nearest point to the polar cap being measured with a micrometer. The varying inclination of this tangent to the horizontal renders necessary the tilting of the observer's eyes in some positions; presuming that this might affect the resulting measures, Mr. Lowell has differentiated the results accordingly, calling them "expurgated" or "unexpurgated" as the time of observation was less or more than three hours after the horizontal position of the tangent.

This was found to make less difference to the final result than that caused by observing the different oppositions.

The results obtained for the position of the pole of Mars are as follows:—

	R.A.	Dec.
Position upon the earth's equator...	315° 32′	54° 51′
Intersection of the Martian equator and Martian ecliptic	85° 56′	24° 32′
Inclination of Martian equator to Martian ecliptic	—	22° 55′

THE STRUCTURE OF METALS.[1]

THE subject of the lecture was the structure of metals, mainly as revealed by the microscope. The first serious application of the microscope to the study of metallic structure was made in 1864 by Dr. H. Sorby, of Sheffield, but the lead then given was not followed for nearly a quarter of a century. In the last fifteen years or so, however, it had been taken up with the greatest zeal and success, nowhere more than in Dr. Sorby's own town. There and elsewhere, in France, Germany, and America, as well as at home, a band of enthusiastic workers had been engaged in creating what might be described as a novel branch of physical science, as interesting on the physical side as it was important in its practical aspect. In this work Cambridge had done its share. The lecturer referred especially to work done in the engineering laboratory by Rosenhain, Humfrey, and other of his own former research students, and to the admirable investigation of alloys carried out by Neville and Heycock in the laboratory of Sidney Sussex College.

It was only possible to give in a single lecture a very brief account of part of this work. Photography had lent its powerful aid in recording what the microscope made visible. By means of lantern slides showing microphotographs of polished and etched metallic surfaces, the lecturer proceeded to exhibit the characteristic structure of a pure or nearly pure metal, where the whole mass is made up of irregular grains with well marked boundaries more or less polygonal in form. The grains could be distinguished from one another not only by the presence of the boundaries, but by differences of texture which were especially conspicuous under oblique lighting. Each grain was a true crystal made up of similarly oriented particles in a perfectly regular tactical arrangement, such as might be exemplified by imagining it to be built up of minute brickbats all of the same form and size. When a polished surface was etched the facets of the elementary brickbats were exposed, and the manner in which these reflected the light into or away from the microscope determined the appearance which the grain presented under oblique illumination. A slight change in the direction of the incident light would greatly affect the brightness of the grain, making it shine out or grow dull, but over each grain there was a uniform degree of brightness due to the uniformity of its tactical formation. Each grain had grown as a crystal, starting from a chance nucleus, and the boundaries were determined by the casual interference of grain with grain in the process of growth. In general, the growth was at first dendritic, skeleton forms shooting out until they met similar growths in neighbouring grains, and the interstices of the skeleton were filled in later. In some metals the grains were products of crystallisation from the liquid state; in others, notably in iron, a re-crystallisation took place long after the metal had solidified, and in such cases the grains, as we knew them under ordinary conditions of temperature, were the result of an internal re-arrangement which took place while the metal was solid. In such cases they were characterised by less regular boundaries, and there was evidence of more intimate interlocking between grain and grain. The structure might be fine or gross; in specially pure metals, and under specially slow conditions of cooling, it was apt to become specially gross. An instance was exhibited of a piece of lead of exceptional purity allowed to solidify by very slow cooling, in which the grains were so large as to be visible to the audience without magnification. Their appearance under oblique lighting was projected on the screen, and by tilting the block of lead the striking changes of brightness due to change in the incidence of the light were exhibited. Other evidences of the crystalline character of the grains were referred to, namely, the pits and geometrical forms developed on the surface by etching, and the geometrical forms assumed by very minute bubbles of gas or air imprisoned in the process of solidification.

Coming next to the consideration of effects of stress, the lecturer described the experiments by which, in conjunction with Mr. Rosenhain, he had demonstrated that the plastic yielding of metals when severely strained is due to a multitude of slips occurring along cleavage planes in the several grains of which the metal is a conglomerate. The appearance of "slip-lines" in various metals was shown, and the character of the lines was discussed. As Rosenhain had recently pointed out, the slip-lines were comparatively straight in grains formed by solidification from the solid (as, for example, in cast lead, silver, and gold), but were broken up into steps which gave them the appearance of being curved in metal which had undergone re-crystallisation while in the solid state. This was ascribed to the more intimate interlocking of the grains in the latter case. That the slips showed themselves by steps or sudden slight changes in the level of the surface was clearly demonstrated when the slip-lines were examined under oblique light. All the parallel slips on a given grain would then flash out simultaneously when the direction of the incident light suited the particular slope of the planes in which the slips had taken place. The form of slips in twin structures was exhibited, and also in an example (due to Humfrey) of lead with a structure so gross that the relation of the slips to the geometry of the grain could be readily traced.

A question of immense practical interest was the "fatigue" which metals underwent when exposed to many repetitions of a straining action. The microscope threw valuable light on this by showing how, under repetition of pulls or pushes or bendings, a piece began to give way, first by slips appearing on isolated grains, and then by some of these slips gradually developing into cracks. Instances were cited from a joint research by the lecturer and Mr. Humfrey. Mr. Rogers, who had pursued this subject with much zeal, had recently found that breakdown by fatigue was much more liable to occur in steel which had been thermally treated in such a manner as to develop a comparatively large structure than in the same steel when the treatment was such as to make the structure normally small.

Going on to speak of alloys, the lecturer described shortly the various ways in which two constituents might combine, or rather act together, in the composition of a binary alloy. In the liquid state each dissolved in the other, in the solid state one might remain wholly or in part dissolved in the other, forming what was called a solid solution. Thus with two constituents A and B, if A were present in small quantity only it might be found wholly contained as a solid solution in B. More generally, however, a solid solution would crystallise out first, leaving a mother liquor richer in A, which, by throwing down more and more solid solution, finally reached the proportion of the "eutectic" alloy, and then solidified as a eutectic mixture, showing under the microscope the zebra-like marking which characterised eutectic alloys. This process was explained by means of freezing-point curves, and was exemplified by a beautiful series of photographs taken by Mr. Stead, showing alloys of various proportional composition in which iron and phosphide of iron were the two constituents. When very little phosphorus was present, the whole solidified as a solid solution showing grains undistinguishable in general appearance from those of a pure metal. With a little more phosphorus the solid still consisted mainly of large grains, but the interstices (or in one case the inner parts of a dendritic skeleton) showed traces of the eutectic, which was the last part to solidify. With more phosphorus still the solid solution showed itself as incomplete skeleton grains interspersed with large quantities of eutectic. With more still the eutectic proportion was reached, and the whole solidified as a eutectic mixture, showing zebra markings all over the surface. With more still—that is to say, with an excess of phosphide—crystals of phosphide were first

[1] Abstract of the Rede lecture delivered before the University of Cambridge, June 11. By J. A. Ewing, LL.D., F.R.S., Hon. Fellow of King's College, Director of Naval Education.

deposited, and the remainder froze as a eutectic in which these crystals were encased. The phosphide crystals showed sharp geometrical outlines, in marked contrast to the outlines of the crystals of solution, because the phosphide was deposited as a definite constituent in which the other constituent (iron) was not soluble.

To explain the zebra markings characteristic of eutectics, Dr. Ewing briefly referred to the phenomenon of surfusion, and gave it as his opinion that the formation of a eutectic occurred by alternate surfusion or supersaturation of each constituent in the other. A eutectic in the fluid state and about to freeze might be defined as a saturated solution of A in B which was at the same time a saturated solution of B in A. On the temperature falling, an alternating condition of instability results. By surfusion, A is at first supersaturated with B, until some of B is thrown down, leaving, in the liquid that remains, B supersaturated with A. Consequently, some of A is in turn thrown down, and so on alternately. In the appearance of a eutectic alloy there was much that was suggestive of alternate deposit of the two constituents, and it was in some such way as this that Dr. Ewing conceived the alternation to take place.

Eutectics in which the constituents were not of the same crystalline system appeared to be mechanically weak. A very small quantity of bismuth added to copper or silver or lead was shown by Arnold to produce great brittleness, owing to the weakness of the cement which the eutectic formed in the joints between the grains, although the individual grains themselves preserved their original malleability. In other eutectics no such weakness, as a rule, was found, and the intergranular cement was as strong as the grains themselves—often, indeed, it was distinctly stronger.

From the engineering point of view, by far the most important alloys were those in which the chief constituents were iron and carbon, or rather iron and carbide of iron. By help of Roozeboom's diagram, the lecturer explained briefly the characteristics of high and low carbon steels, and the transformations which occur in the process of cooling at temperatures far below that at which the metal becomes wholly solid, which had formed the subject of much study by Osmond, Roberts-Austen, and others. By the process of quenching these changes might be to some extent arrested, and the mechanical properties secured which characterise hardened steels. The evolution of heat in the transformation was illustrated by means of cooling curves, and by experiments in which steel wire was allowed to cool after being electrically heated above the transformation points. While passing through the region in which transformation occurs, the steel is specially plastic; this was illustrated in the cooling from bright redness of a steel wire coiled into the form of a spring and carrying a light weight. The spring extended in a conspicuous way while the process of re-crystallisation associated with "recalescence" was going on. The phenomenon of recalescence was further illustrated in an automatic record obtained during the lecture with a Callendar recorder which was exhibited by the Cambridge Instrument Company. The recent results of Carpenter and Keeling, in their research at the National Physical Laboratory, were referred to as giving in most particulars a general confirmation of Roozeboom's views. Other examples of transformation occurring in the solid state were illustrated by photographs selected from Neville and Heycock's series for the copper-tin alloys.

The gradual changes of structure which go on even at atmospheric temperatures in lead and other metals after the structure has been broken up by severe straining were next described, photographs by Rosenhain and the lecturer being exhibited to demonstrate the progressive character of these changes, and the manner in which they would be accelerated by elevating the temperature.

In conclusion, the lecturer referred to the analogous case of glacier ice. It had for long been known to possess a granular structure, and each grain was a crystal just as in the case of metals. Photographs by Principal Skinner, illustrating this granular structure, were shown. In the upper névé the grains were vague and comparatively small; as the glacier slowly travelled down the grains became consolidated and large, and their outlines became well defined. It was clear that a slow process of crystal growth was going on, and in the lecturer's opinion it was to this very process of growth that the plasticity of the glacier as a whole was to be ascribed. How ice came to be plastic in large masses was a question to which physicists had suggested more than one answer. But the plasticity was intelligible enough when one realised that the whole mass was in the act of structural change. Just as the spiral spring in the experiment with steel showed during its transformation a special plasticity, so the glacier showed a general plasticity throughout its course, inasmuch as it was undergoing a slow and probably continuous structural change in the crystallisation of its individual grains. Alike in the metal and the ice, nature was apparently following one structural process, and the consequences as to plasticity were alike in both. In neither case was any constancy to be found save the constancy of change. Nothing was more striking to a worker in this field than the evidence he found that those substances on which we were most accustomed to rely as constant were undergoing, sometimes comparatively fast and sometimes very slowly, a process of internal flux. A monument more enduring than brass might be a lofty ideal, but it was seen at least to be an ideal easy of conception when one realised how far from constant the inner structure of brass and other metals was apt to be.

THE GAS SUPPLY OF THE METROPOLIS.

A committee was appointed by the Board of Trade in January last to inquire and report as to the statutory requirements relating to the illuminating power and purity of the gas supplied by the metropolitan gas companies, and as to the methods now adopted for testing. The report of this committee has now been presented, after hearing evidence from the metropolitan gas referees, from representatives of the London County Council, the Corporation of the City of London, and each of the three gas companies concerned.

The supply of gas in the metropolis being a monopoly, provision is made in the private Acts of the various companies for securing the maintenance of certain standards of purity and illuminating power. Three gas referees are appointed by the Board of Trade, with power to prescribe and certify the situation and number of testing places to be provided, and to lay down the conditions under which the testings are to be made. By the insertion of clauses in recent Acts obtained by the gas companies bearing on the mode of testing, these powers have been somewhat curtailed. The testing places are usually fitted up in houses owned or leased by the gas companies, the tests being made by officials appointed by the controlling authority, either the London County Council or the Corporation of the City of London. A comparison of the tests made at the official stations with tests made with a portable photometer in the neighbourhood of those stations having shown considerable discrepancies, attempts have been made by the controlling authority to legalise the portable photometer, but these attempts have been successfully resisted by the gas companies before Parliament, and the present committee in the report is not prepared to recommend the adoption of such tests. As, however, these results have given rise to doubt as to whether the gas supplied to the testing stations really represents the gas supplied to the public, the gas referees have laid down a requirement that the gas to be tested is to be brought direct from the main to the testing place by a single service pipe, without tap or branch or provision for connection of any kind outside the testing place. This has been strenuously resisted by one of the companies, and has led to the curious result that, although the referees have powers to prescribe testing places, they have no powers to enforce their prescription, and owing to the deadlock thus created two testing places have remained closed for some years.

The committee is of opinion that this requirement is a reasonable one, and that it might with advantage be made a statutory requirement not dependent on the prescription of the gas referees.

In the case of any deficiencies being found by the official examiners, action is taken by the controlling authority before a magistrate, with a view to the recovery of the forfeitures specified in the Acts. If any technical objection is raised by the gas companies, the question is referred to

the chief gas examiner (Lord Rayleigh), and unless the appeal is sustained the case is referred back to the magistrate for the assessment of the amount to be paid. The gas companies have always strongly objected to these police court proceedings, and the committee recommends a modification of the existing provisions whereby, in future, police court proceedings will not be required when the chief gas examiner shall certify that the default is not substantial, or that it is not due to careless conduct at the works, the forfeitures in all such cases being left for assessment to the chief gas examiner. The committee also recommends that in the case of any disputes arising between the gas referees and the gas companies, they should be referred to the chief gas examiner, and that his decision should be conclusive and binding on both parties.

Important concessions to the companies are recommended by the committee with regard to the amount of sulphur impurity allowed. In addition to a relaxation of the stringency of the tests to be applied for the detection of sulphuretted hydrogen, it is suggested that the standards for the amount of sulphur present in the gas, other than sulphuretted hydrogen, should be abolished. The committee has been influenced in this decision by the consideration of the nuisance created near the works by the use of lime purification, and the danger to the men employed in connection with the process. At the same time, however, it is proposed that the official tests should continue to be made, and that the amount of impurity in each form contained in the gas should be ascertained and recorded.

In view of the increasing amount of gas used in incandescent burners and for heating and power purposes, it is considered desirable that the calorific value of the gas should be determined and recorded, but no standards are proposed, and photometrical data with flat flame burners, in addition to those already made with the standard Argand, are also suggested as desirable.

The report has been issued within five months of the date of appointment of the committee, and it is to be hoped in the interests of the public that the legislative action necessary to carry these suggestions into effect may be made with equal promptness.

SEISMOLOGICAL NOTES.

IN the *Bollettino della Società Sismologica Italiana*, vol. ix., No. 7, Dr. A. Ricco gives an interesting paper on the relative values of gravity in the vicinity of Etna, Sicily, the Æolian Islands, and southern Italy. The results are shown in two sketch maps, on which a series of lines having the appearance of isomagnetics pass through places at which the difference between the expected and the observed values for g are equal. The smallest values for the anomaly or $g-\gamma$. are found round the summit of Etna, whilst maxima occur in the proximity of deep water about 80 km. to the south-south-west and 150 km. at Stromboli to the north. A similar but not so marked gradient is found in the vicinity of the Bay of Naples. Along the Apennines and in central Sicily the anomaly is small, and the gradient is gentle. These observations are discussed in relation to volcanic and seismic activity, orographic and geotectonic conditions. An obituary notice of Dr. Mosé Contarini, who died at the early age of twenty-eight, at the commencement of a promising career, and a catalogue of disturbances for July, 1902, complete the number.

In vol. ix., No. 8, of the same publication, Dr. A. Cancani describes and analyses five seismograms relating to earthquakes with known origins. The peculiarity of these seismograms, copies of which are given, is that they were obtained on a high speed (72 to 97 mm. per minute) smoked paper record receiving surface.

The diagrams are therefore sufficiently open to read periods of half a second, which periods refer to the preliminary tremors. From the interval in time between the commencement of these first movements and the commencement of the large waves, the distances of origins from Dr. Cancani's station in Rome are calculated. The accuracy of the results obtained therefore depend upon the accuracy with which these two phases of motion can be identified upon the seismograms. In the first earthquake considered these identifications are clear, but if the figures for the remainder are exact reproductions of the original seismograms, it seems extremely likely that very different results might be arrived at by different investigators. For writing pointers with a minimum of friction, Dr. Cancani uses the hanging aluminium indices of his colleague, Dr. Grablovitz. The cost per annum for the recording materials, which include 730 sheets of paper, gas or oil for smoking, and varnish for fixing the same, &c., is about 3*l.* 15*s.* At the end of the number the earthquake registers are brought up to the end of August, 1902.

The Austrian Earthquake Commission publish in No. 22 (new series) observations made by Dr. W. Láska in 1902 in Lemberg. They refer to records obtained from Reubeur-Ehlert horizontal pendulums.

In the *Mémoires* of the Geological Committee of St. Petersburg, No. 9 (new series), Dr. V. Weber gives a detailed account of the earthquake which on January 31, 1902, destroyed Chemaka. The epifocal area appears to lie along the major axis of a series of elliptical isoseists, and a map on which these are shown also indicates the different degrees of destruction in various villages within the disturbed district.

The phenomena observed are similar to those noted with many large earthquakes.

Another publication received from Russia is the *Bulletin* de la Commission Centrale Sismique Permanante. It refers to records obtained in the months April, May, and June at Tiflis, Taschkent, Irkutsk, Dorpat, and Krasnoiarsk, at each of which stations there are one or more seismographs.

The contributions to seismological knowledge received from Japan are as usual both varied and interesting.

Following in the footsteps of Dr. C. G. Knott, Mr. A. Imamura, in the reports of the Physico-Mathematical Society of Tokyo, vol. ii., No. 8, discusses certain earthquake registers, with the result that he finds that seismic disturbances have not only been most frequent at the times of conjunction and opposition of the sun and moon, but also at the times of quadrature. The extent to which barometrical pressure may effect seismic frequency is to be found in the same journal, the author being Dr. F. Ōmori. Another note by the same writer describes a horizontal pendulum controlled by an inverted pendulum. The former is 1 m. in height, and has a boom 1 m. in length which carries 50 kg. With its control a period of one minute is obtained without difficulty.

Dr. Ōmori's most important work is contained in No. 15 of the *Publications* of the Earthquake Investigation Committee. It relates to the measurement of the vibrations of railway carriages as recorded by seismographs. For years past the balancing of locomotives and the state of the permanent way have in Japan been determined by means of these instruments, and the practical advantages leading to the saving of fuel and the detection of faults which have accrued are generally known. Here we have an elaborate extension of previous work which railway engineers may read with advantage.

At the end of this number an index is given to the contents of the sixty-three profusely illustrated series of volumes and parts which, since 1893, have been issued by the Tokyo Earthquake Investigation Committee. Unfortunately for European readers, forty-seven of these publications are in Chinese idiographs. Amongst the latter we find reports upon seismographs, observations made in deep bore holes, notes upon magnetic disturbances which have preceded certain large earthquakes, many observations made for the purpose of determining the transit velocity of earthquake motion, observations relating to subterranean sound phenomena, observations upon sea waves, investigations relating to seismic frequency, reports upon faults, landslips and volcanoes, and a mass of material, all the result of patient investigation, which is of great importance to modern science. Many of the papers are of immediate value to those who have to construct in earthquake countries. Not only has the Japanese Government encouraged its engineers to study the effects of earthquakes upon structures within its own territory, but lengthy reports upon the damage which took place in Assam in June, 1897, indicate that it was considered advisable to derive lessons from misfortunes in foreign countries, and for this reason missions of

engineers and men of science have been sent not only to India, but to Manila, Italy, and other places. One set of instructive reports refers to destruction and shattering produced by movements closely approximating to those of actual earthquakes given to a platform on which masonry and other structures had been erected. This platform is in no sense a toy, but a large piece of apparatus actuated by powerful machinery. To say that these investigations have during the last ten years cost the Government of Japan 50,000*l*. is a modest estimate. The return for the same is seen in the new types of structures which are growing up in Japan, replicas of which have been adopted in British possessions and other places, the meaning of which is that danger to life and property resulting from seismic disturbances, if not averted, has been markedly mitigated.

Add twenty volumes issued by the Seismological Society to those published by the Investigation Committee, and we have eighty-three publications, the greater number of which are volumes, as Japan's contribution to recent seismological progress.

In consequence of not being acquainted with researches carried out in the Far East—and we do not refer to those which Japan for the benefit of her own people has published in Chinese characters—it is not uncommon to find seismologists in Europe reproducing as novelties the *faits accomplis* of past history. Had Prof. Odone read the *Transactions* of the Seismological Society of Japan, it is not likely that in a recent number of the *Bollettino* he would have given, with drawings almost identical with those published in Japan, a description of a method by which the relative motion of two points of the earth's surface might be measured; neither should we find in the last number of the same journal a description, quoted from the *Comptes rendus*, January 26, 1903, of a new system by which record receiving surfaces could be set in movement, and therefore ready to receive the record of an earthquake before the earthquake itself arrived to actuate the indices of a seismograph. In 1884 in Japan nine stations were electrically connected, so that an earth movement at one of them resulted in the release of clockwork at all the others (*Trans.* Seis. Soc., vol. x.).

Since then the system has been greatly extended, and at stations considerable distances apart record receiving surfaces are set in motion before the pointers resting on the same have been actuated by earth movements. That work of this description, which was referred to over and over again in publications issued twenty years ago in Japan, should in 1904 be reproduced in Europe as original indicates that the work has at least had some slight recognition. The main point at issue, however, is that the veil of Chinese cryptograms which has hidden so very much of the work done in the Far East has by means of an index been partly raised, and if at Strassburg or at any other institution this work can be rendered available to seismologists who read a European language, the same will from "many an error free us," and be most gratefully received.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The following appointments of university lectures are announced:—Chemistry, Messrs. W. J. Sell, F.R.S., and H. J. H. Fenton, F.R.S.; organic chemistry, Mr. S. Ruhemann; petrology, Mr. A. Harker, F.R.S.; invertebrate morphology, Mr. A. E. Shipley, F.R.S.; physical anthropology, Mr. W. L. H. Duckworth; palæozoology, Mr. H. Woods.

The new Balfour student is Mr. R. C. Punnett, of Caius College. A grant of 50*l*. from the Balfour fund has been made to Mr. L. Doncaster, King's, in furtherance of his researches on sex and heredity.

Messrs. C. Shearer and W. E. Agar have been nominated to occupy the university's table at the Naples Zoological Station.

The special board for biology proposes that Mr. J. W. Clark should be re-appointed a manager of the Balfour fund for a period of ten years.

The original researches of Messrs. R. Hosking, W. Makower, G. Owen, and F. Rogers, advanced students in experimental physics, and in engineering, have been approved by the special board for physics and chemistry as of distinction; they will receive certificates qualifying them for the B.A. degree for research.

Five candidates have gained the university diploma in agriculture; seven have qualified in the first part of the examination.

Mr. H. M. Chadwick, Clare, Mr. C. H. W. Johns, Queens', Dr. A. Macalister, St. John's, and Dr. F. H. H. Guillemard, Caius, have been appointed members of the new board of anthropological studies.

Dr. D. MacAlister, St. John's, has been appointed assessor to the regius professor of physic. Prof. Darwin, Trinity, and Prof. Larmor, St. John's, have been appointed electors to the Isaac Newton studentship in astronomy and physical optics.

MR. PERCY F. KENDALL has been appointed professor of geology in the University of Leeds, and Dr. J. B. Cohen has been appointed professor of organic chemistry in the same university.

MRS. AMANDA W. REED has, says *Science*, provided in her will for the foundation of an institution at Portland, Oregon, to be known as Reed Institute, in memory of her husband, the late Simon G. Reed. The bequest will amount to about 400,000*l*. Her will specifies that the institute shall combine instruction in the fine arts, sciences, and manual training, and that it shall be conducted with especial regard to the needs of young men and women compelled to earn their own living.

NEW science buildings, which by special permission of Lord Kelvin have been called the Kelvin Science School, are to be opened by Sir Douglas Fox at Trent College, Derbyshire, on June 29. The new science school contains six large rooms and three small ones; these include a room for manual instruction in wood and iron, a physical laboratory, a lecture theatre to seat eighty, a balance room, a chemical laboratory for twenty-four students, and a biological laboratory for sixteen students.

A PAPER read by Prof. Israel C. Russell before the Research Club of the University of Michigan in January last is printed in *Science* for June 3. After referring to the triumphs of science in the last century, Prof. Russell remarked:—"The intellectual tide-gauges of the world give no suggestion that the nineteenth century wave of discovery has culminated. On the contrary, there is abundant evidence to show that the rate of intellectual development is still on the increase, and that yet more important conquests in the domain of the unknown than have illuminated the past will be made in the future." The recognition of the importance of research by the United States is naturally emphasised in the paper, and three important steps in this direction are marked by what Prof. Russell called "enduring movements," viz. the *American Journal of Science*, which appeared first in 1818, the Smithsonian Institution, and the Carnegie Institution. Speaking of the place of research in the university, Prof. Russell expressed his agreement with the dictum of Sir Norman Lockyer, that "research is now generally acknowledged to be the most powerful engine of education that we possess."

THE twenty-eighth annual exhibition of work executed in the public elementary schools founded by the late London School Board, and now administered by the London County Council, was held from June 13 to 18 at the Medical Examination Hall, Victoria Embankment. As in previous years, one section of the exhibition was devoted to the science work done in these schools. The exhibits were chiefly pieces of apparatus and working models made or arranged by pupils and teachers. It was satisfactory to notice that the work of pupils and teachers was this year kept separate, and the confusion which in some former years resulted from an indiscriminate intermingling of the exhibits of teachers and taught was fortunately avoided. Much of the work shown was the joint product of the science

departments of the schools and of the manual training centres, and the standard of excellence attained may be taken as proving that good results follow the correlation of the instruction in science and in manual work. The total number of exhibits was unusually small, and it is difficult to find a reason for the inclusion among them of scientific instruments obtained from manufacturers. The collection of exhibits, though interesting and from some points of view satisfactory, did not succeed in conveying an adequate idea of the work in science accomplished in the schools. The man of science interested in education would have obtained a better general idea of the scope of the science work in the council's day and evening schools had typical laboratory note-books and typical syllabuses of work done been exhibited. There was, however, evidence enough to show that the claims of science to a place in the curriculum of the public elementary schools of London are recognised by the London Education Committee.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 2.—"On the Magnetic Changes of Length in Annealed Rods of Cobalt and Nickel." By Shelford **Bidwell**, F.R.S.

The magnetic changes of length in annealed iron were described by the author in 1894 (*Proc.* Roy. Soc., vol. lv. p. 228). When subjected to a longitudinal field gradually increasing from a small value, an ordinary iron wire is at first extended, then it recovers its original length, and finally becomes shorter than when unmagnetised. In annealed iron the maximum extension is diminished, and contraction begins in a weaker field, the change-of-length curve being lowered. In the case of a thoroughly well annealed specimen, contraction began in a very weak field without any preliminary extension. Similar experiments have now been made with cobalt and nickel. Cobalt in the ordinary condition behaves oppositely to iron, contracting in weak fields and lengthening in strong ones. It was found that a well annealed rod of cast cobalt contracted uniformly in fields up to 1360 units (the highest reached), the retraction curve being a straight line. This confirms an observation published last year in Japan by Honda and Shimizu. For a specimen of rolled cobalt, however, the change-of-length curve retained its general form, but was considerably lowered; in a field of 1750 the ascending limb was still below the axis of H and nearly parallel to it; probably, therefore, there would never be any elongation, however strong the field. The most noteworthy effect of annealing upon the retraction curve for nickel is an increase in the abruptness of its descent, which may be due merely to greater magnetic susceptibility. Thus it appears that well annealed specimens of iron, cobalt and nickel all undergo contraction when longitudinally magnetised.

Mineralogical Society, June 7.—Dr. Hugo Müller, president, in the chair.—The Rev. Mark **Fletcher** contributed a note on mispickel from Sulitjelma Mine, Norway, containing about 1·32 per cent. of cobalt, and showing the forms {011}, {012}, {110}.—Mr. G. F. Herbert **Smith** exhibited a hand-refractometer of the Bertrand type, in which the curvature of the focal surface had been reduced by means of a correcting lens, with a consequent improvement in the definition of the shadow edges.—Prof. H. A. **Miers** gave an account, illustrated by numerous lantern slides, of the development of the Kimberley Diamond Mines. He traced the changes in the methods of working from the first surface diggings to the time when the blue-ground was brought to the edge of the pit by a "cobweb" of wire ropes stretching from the numerous independent claims into which the mines were split up, and showed how the increasing difficulties involved in this method led to the final consolidation of the mines under Beit and Rhodes, and to the initiation of the present system of mining, which consists in sinking shafts on the edge of the pit, and running cross-cuts into the blue-ground. He referred finally to the recent discovery of blue-ground in the neighbourhood of Pretoria.

Faraday Society, June 9.—Dr. J. W. Swan, president, in the chair.—The electric furnace: its origin, transformations and applications, part i.: M. Adolphe **Minet**. The paper discusses the growth of the furnace from the historical point of view, and then proposes a new classification, which is worked out in minute detail in the form of a table. A full bibliography of the electric furnace completes this section of the paper.—A form of porous diaphragm convenient for laboratory use: Dr. F. M. **Perkin**. It consists of two perforated concentric porcelain cylinders packed in between with brown paper, asbestos, or other material, depending on the use to which the diaphragm is to be put.—The hard and soft states in metals: G. T. **Beilby**. The views advanced by the author are based on his earlier observations on surface flow in crystalline solids. The evidence afforded by the micro-structure has been supplemented by observations on the other properties of metals in the hard and soft states, and the view is now advanced that these states are perfectly distinct phases. This is shown by the mechanical, electrical, optical, and thermochemical properties, as well as by the micro-structure.

Royal Meteorological Society, June 15.—Capt. D. Wilson Barker, president, in the chair.—Effects of a lightning stroke at Earl's Fee, Bowers Gifford, Essex, April 13: Rev. C. F. **Box**. A thunderstorm occurred during the early morning hours, and about 3 a.m. there was a blinding flash, lighting up the whole neighbourhood for miles around, followed immediately by a crashing explosion. One person stated that he saw what appeared to be a cylinder, and another person a ball of fire, descend and then explode, "casting darts" in all directions. On careful examination in daylight, it was found that in an oatfield, which had recently been dredged, there were three distinct sets of holes ranging from 9 inches down to about 1 inch in diameter. The holes, which were perfectly circular, diminished in size as they went downwards, and remained so on to the perfectly rounded ends at the bottom. Upon digging sectionally into the soil, which is stiff yellow clay, it was found that the holes were "as clean cut as though bored with an auger." An interesting discussion followed the reading of this paper.—An instrument for determining the true direction and velocity of the wind at sea: A. Lawrence **Rotch**.

PARIS.

Academy of Sciences, June 13.—M. Mascart in the chair.—Muscular displacement applied to carrying a load without displacement, the statical work of muscle. The comparison of this internal work with the resulting expenditure of energy, and influence of the magnitude of the load: A. **Chauveau**. Use was made of the respiratory coefficient in measuring the energy expenditure, and this was found to increase faster than the load sustained, although for small loads these were found to be nearly proportional.—The influence exercised by small variations of external actions on a system affected by hysteresis and defined by two variables: P. **Duhem**.—On the property possessed by a considerable number of bodies of projecting a ponderable emanation spontaneously and continuously: R. **Blondlot**.—A photographic study of the spectrum of the planet Jupiter: M. **Millochau**. The photographs were taken with a spectrograph attached to the large telescope of the Observatory of Meudon (84 cm. diameter), and the spectra obtained extended from the F line to the C line, means being taken to allow of a comparison of the spectra from the bands with that from the other parts of the disc. The presence of water vapour is clearly proved.—Remarks on the preceding communication: J. **Janssen**.—On a class of differential equations with multiform integrals: Pierre **Boutroux**.—Energy in statical reactions: Eugène **Lebert**. A discussion of the results of M. Chauveau on the "statical work" of muscle.—On the index of refraction of solutions: C. **Chéneveau**.—Contributions to the study of the n- and n_1-rays: Jean **Becquerel**.—On the forms of high frequency lighting between platinum wires of small diameter: André **Broca** and M. **Turchini**.—The action of the n-rays on pure water: Julien **Meyer**. Experiments are described leading to the conclusion that pure water, submitted to the action of the n-rays, becomes itself a source of n_1-rays.—On the measurement of the mobility of the ions in gases by a null method: Eugène **Bloch**. The method of MacClelland, improved by Zeleny, is modified by conversion into a null method, which much extends the field of its application.—The atomic weight of nitrogen: the analysis of nitrogen

monoxide by weight: Ph. A. **Guye** and **St. Bogdan.** The ratio of nitrogen monoxide to the oxygen it contains, determined gravimetrically, gives a value 14·007 for the atomic weight of nitrogen.—On the decomposition of a mixture of calcium carbonate and an alkaline carbonate under the action of heat in a vacuum: P. **Lebeau.** The decomposition by heat in a vacuum of mixtures of calcium carbonate and the carbonates of cæsium, rubidium, potassium, and sodium was complete. The amount of carbon dioxide obtained corresponded exactly to the amount of carbonates taken, and in all cases pure calcium oxide was left behind.—On some cuprous salts: A. **Joannis.** Details are given of the preparation of cuprous formate and benzoate.—On a basic ferric phosphite: E. **Berger.**—On the alloys of magnesium with bismuth and magnesium: Hector **Pécheux.**—Iodine compounds obtained with metanitraniline: P. **Brenans.**—On a spontaneous alteration product of oxalacetic ester: L. J. **Simon.** A sample of oxalacetic ester which has been kept for some time gives a violet colour reaction when placed in contact with an alkaline solution. This is not given by the freshly prepared substance, and is probably due to a dioxyquinone, formed by the elimination of one molecule of water between two molecules of oxalacetic ester.—Polyacid salts of rosanilines: Jules **Schmidlin.**—On the variations shown in the composition of seeds during their maturation: G. **André.**—The distribution of some organic substances in orange flowers: Eug. **Charabot** and G. **Laloue.** The petals contain the greater part of the essential oil.—On zymase and alcoholic fermentation: P. **Mazé.**—On *Mitsukurina Owstoni*: Léon **Vaillant.** This only differs from the elasmobranchs, with which it has been compared, by characters of the second order, and the author regards it as belonging to the family of Lamnidæ. This is not in accord with the views of Jordan, who regards it as a distinct type.—On a transformation of the tentacular apparatus on certain species of Madrepora: Armand **Krempf.**—Some polytaxic characters in species in the wild state: G. **Coutagne.**—Chains of force: M. **Hartog.** A description of a model reproducing certain phenomena of cell formation by the motion of magnetisable particles placed in a magnetic field in a viscous medium.—On the morphology of the root of plants with mutilated embryo: P. **Ledoux.**—The discovery of fossil-bearing layers in Djoua, to the east of Timassanine, Sahara: F. **Foureau.**—On the fauna of the Cretacean Ceratodus layers of Djoua, near Timassanine, Sahara: Émile **Haug.**—On the fauna of the Lydian of the Vosges sandstones: C. **Nöel.**—The survival of a negroid type in the modern populations of Europe: Eugène **Pittard.** The examination of skulls from the Rhone Valley, dating from the thirteenth century up to the commencement of the nineteenth century, shows evidences of a well marked negroid type, which may be a simple survival or a case of atavism.—The structure of the muscular fibres of the heart in molluscs: Pierre **Vigier.**—On the muscular fibres of the heart in *Nassa reticulata*: M. **Mader.**—The effect of the chromatism of the eye in colour vision: A. **Polack.**—A new example of physical adaptation between a natural stimulus, a sound vibration, and a central perceptive organ: Augustin **Charpentier.** By the use of phosphorescent screens a third example is given of an influence exercised directly by a natural agent upon the corresponding nervous centre.—The action of the *n*-rays upon an isolated nerve trunk: Paul L. **Mercanton** and Casimir **Radzikowski.** The sciatic nerve of the frog is not excitable by exposure to the *n*-rays.—Researches on the physiological effects of radium: C. J. **Salmonson** and G. **Dreyer.**—The relations between intra-organic combustions and the proportion of oxygen contained in the arterial blood: J. **Tissot.** Intraorganic combustions, measured by the values of the respiratory exchanges, are independent of the proportion of oxygen contained in the arterial blood.—Researches on the blood of Selachians. The toxic action of the blood of *Torpedo marmorata*: E. **Gley.**—The use of calcium sulphide against dodder and other injurious parasites: F. **Garrigou.**

NEW SOUTH WALES.

Linnean Society, April 27.—Mr. Thomas Steel in the chair.—Descriptions of new species of Australian Coleoptera, part vii.: A. M. **Lea.** Thirty species are described as new. Three previously unnoticed blind species from Tasmania are recorded—*Annomatus 12-striatus*, Müll., introduced from England, probably with pot plants; *Phycochus graniceps*, Broun, found also in New Zealand; and *P. sulcipennis*, n.sp. The number of blind species known from Australia and Tasmania is thus brought up to a total of eight.—Contributions to a knowledge of Australian Entozoa. No. iii. On some species of Holostomidæ from Australian birds: S. J. **Johnston.** Five species, all parasites of Australian birds, are described as new.—Australian fungi, new or unrecorded. Decades vii.–viii.: D. **McAlpine.** Of the twenty species recorded, seventeen, referable to thirteen genera, are described as new. Myriangium, formerly classed with the lichens, is represented by two species, and a new genus, Amphichæta, allied to Monochæta, Sacc., is proposed. The favourable condition of the specimens examined has made it possible to give a description of the spores of a species of Hexagonia—apparently the first to be recorded.

DIARY OF SOCIETIES.

FRIDAY, JUNE 24.

PHYSICAL SOCIETY, at 5.—Chemical Dissociation and Electrical Conductivity: A. E. Garrett and Dr. R. S. Willows.—The Magnetisation of Iron in Bulk: Dr. W. M. Thornton.

MONDAY, JUNE 27.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—The Anglo-French Boundary Commission in Nigeria: Colonel G. S. McD. Elliot, R.E.

CONTENTS. PAGE

THURSDAY, JUNE 30, 1904.

MATHEMATICAL BOOKS.

(1) *An Introduction to the Study of Geometry.* By A. J. Pressland, M.A., F.R.S.E. Pp. 40. (London: Rivingtons, 1904.) Price 1s.

(2) *Elementary Geometry.* By Cecil Hawkins, M.A. Part i. Pp. viii+165. Part ii. Pp. 166–296. (London: Blackie and Son, Ltd., 1904.) Price 2s. each volume.

(3) *Geometry for Technical Students.* By E. H. Sprague, Assoc.M.Inst.C.E. Pp. viii+60. (London: Crosby Lockwood and Son, 1904.) Price 1s.

(4) *Graphs and Imaginaries.* By J. G. Hamilton, B.A., and F. Kettle, B.A. Pp. 42. (London: Edward Arnold, 1904.) Price 1s. 6d.

(5) *Five-figure Tables of Mathematical Functions.* By John Borthwick Dale, M.A. Pp. xvi+92. (London: Edward Arnold, 1903.) Price 3s. 6d. net.

(6) *Logarithms for Beginners.* By Charles N. Pickworth. Pp. 47. (London: Whittaker and Co., 1904.) Price 1s.

(7) *Calculating Tables.* By Dr. H. Zimmermann. Translated from the German by L. Descroiz. Pp. xxxi+204. (London: Asher and Co., 1904.) Price 6s. net.

(1) MR. Pressland adopts the heuristic method in this course of experimental geometry for beginners. The first exercises only require the use of a pencil and a graduated straight edge cut from ruled school paper. With these the boy draws triangles and quadrilaterals, bisects lines and erects perpendiculars. Symmetrical figures, such as the square, rhombus, kite, &c., are made by paper folding.

A ruler with two edges decimally subdivided into inches and centimetres is then introduced, together with two set squares and a protractor. Parallel and perpendicular lines are now readily drawn, and the work becomes quantitative, lengths, angles, and also areas being measured.

The pupil is next required to use compasses, and becomes acquainted with some properties of circles. Two or three pages are then given to proportion and graphic arithmetic. The book concludes with a set of examples in practical geometry, and a table of general properties of figures, only partially enunciated, and intended to be completed by the pupil himself from observation and discovery in the course of his experimental work.

The aim has been to train the hand and eye, to create interest, and to make the boy acquainted with the groundwork of the subject. Deductive geometry is not introduced, nor is there any attempt at a logical sequence. The author states that many features of his book are due to his experience as an inspector of schools in Canton Zürich. The course seems a good one within its limited sphere, but the experimental work might with advantage have been somewhat more extended and varied.

(2) In so far as the subject is dealt with, Mr. Hawkins's geometrical course is a very good one. It is confined to plane geometry, part i. relating to simple rectilineal figures and the circle, and part ii. dealing more particularly with areas, proportion, similar figures, and further properties of the circle. The author follows the reform movement, the propositions required for the Previous Examination under the new Cambridge syllabus being marked with an asterisk. A prominent feature of the work is the very large number of examples which are given, extending to upwards of 1500, of varied character, and affording ample choice for practice in experimental, practical, and theoretical work. The only thing lacking is a collection of the numerical answers. The examples are appended to the successive propositions, and in addition, at the end of each volume is a set of miscellaneous examples, carefully graduated, and covering the whole of the previous ground.

By omitting any reference to simple functions of angles, the author has deprived himself and his readers of a very instructive and fruitful field for examples in ratio and proportion, and of elementary calculations of right angled triangles; and the omission of solid geometry leaves the course incomplete. But the general scheme is well planned and developed, and the book cannot fail to give satisfaction to many readers.

(3) The plan of Mr. Sprague's book is based largely on experience gained by the author in the teaching of engineering students for the Chinese Government, and is intended more especially for those who take up geometry as part of their professional training as engineers.

The more important fundamental properties of plane figures, including the triangle and circle, and of simple geometrical solids are established by deductive methods, comprised in forty-eight propositions with corollaries, and accompanied by a few exercises, and the book concludes with fourteen problems in practical plane geometry.

In comparison with many recent manuals, this textbook seems to be deficient. It will not satisfy those who require a good theoretical course of elementary geometry, nor yet others who are more interested in the experimental and practical development of the subject, and the work is not likely to be generally adopted by any class of students.

(4) In graphing the parabola $y=ax^2+bx+c$, the object being to solve the quadratic equation $ax^2+bx+c=0$, the authors show that when the roots are unreal, say $\alpha\pm i\beta$, the points $\alpha\pm\beta$ lie on a second parabola. The latter is easily drawn, being the former turned into a new position, and α and β can then be measured. In like manner the coordinates of the imaginary points where an external line cuts a parabola are shown to be readily found by making use of the properties of a certain companion or "shadow" parabola.

The authors then give the "circle method" of solving a quadratic, and by means of a "shadow" circle extend the solution to the case of unreal roots. Further examples of shadow circles are given, applied to the imaginary points of intersection or contact of lines and circles. The constructions are curious and interesting, but of little or no value to young students, whose time should not be employed on them.

(5) Mr. Dale's tables have been compiled with the view of meeting the requirements of workers in physical science and applied mathematics, and exclude such functions as are of use only in navigation. They comprise tables of common and hyperbolic logarithms, of reciprocals, squares, cubes, square roots, and cube roots; natural and logarithmic functions of angles; elliptic, Bessel, gamma, exponential, and hyperbolic functions; zonal surface harmonics and some other tables.

The table of logarithms of numbers is modelled on the ordinary four-figure log tables now so largely employed. It has the same number of rows of figures, the mean differences for each row being given, and it occupies only three pages. From it the five-figure log. of any three-figure number can be read directly. For a four-figure number the tabulated difference would require to be added, and for a five-figure number an additional difference for the last figure must be added. In the early part of the table the mean differences vary so quickly as to be of no use for five-figure accuracy, and, indeed, here the fourth figure is scarcely trustworthy. In such cases the author ingeniously recommends the use of the table of anti-logs, in which at the corresponding region the differences vary slowly.

The tables of trigonometrical functions each take up four pages. Five-figure values are given for intervals of $3'$ or $0^{\circ}.05$, and the mean differences for each row are given for $1'$ and $2'$.

Probably these five-figure tables of logarithms and functions of angles are not quite so convenient in use as the more lengthy five-figure tables provided with a thumb index. But occupying as they do only about one-tenth the space, the author has been able to include in a handy volume, at a moderate cost, tables of many transcendental functions which hitherto have not been very readily accessible, and they will be welcomed by the class of people for whom they are intended.

(6) Mr. Pickworth states that the object of his little book is to give a more detailed and practical explanation of the use of logarithms than is to be found in the text-books of algebra and trigonometry. The ordinary two-page tables of four-figure logarithms and anti-logarithms of numbers are given, and the detailed explanations are accompanied by exercises for practice, the answers to which are collected at the end. There is also a short table of the logarithms of some numbers which are of frequent occurrence in numerical work.

Students who are being taught practical mathematics at the present time, and who use a suitable modern text-book, will find in the latter all the information they need on the subject, without having recourse to a book like Mr. Pickworth's. The work seems specially adapted to meet the case of those who received their mathematical training at a time when logarithms were neglected or relegated to the higher branches, and who wish to be able to use this method of computation.

(7) In the preface the author of these tables expresses the opinion that the ordinary aids to arithmetical calculation, such as slide rules, tables of logarithms, &c., are not adapted for general use. Thus he states that logarithms are only understood by very few, that they involve considerable trouble in searching the pages, and that they are seldom employed except for trigonometrical work. However true this may be of Germany, it is scarcely applicable to this country at the present time, where, thanks largely to the influence of South Kensington, logarithms are being taught to large numbers of youths in the classes for practical mathematics, and four figure log tables are in very general use throughout the kingdom.

The author's plan of meeting the common want of the computator is to supply a large multiplication table, which covers 200 pages and goes up to 100 times 1000. That is, the product of any two numbers one of which contains not more than three digits, and the other not more than two, can be taken directly from the table. Running along the bottom of the pages is a table giving, for three-figure numbers ranging from 0.1 to 99.9, the square and square root, cube and cube root, reciprocal, logarithm, and the products $\pi n/2$ and $\pi n^2/4$. On the last two pages are several useful subsidiary tables. In the introductory pages the uses of the tables are fully explained and illustrated with examples, worked out. It is shown how to deal with numbers of more than three digits, and how to perform division, square and cube root, &c. One advantage in the use of these tables is that the calculations are readily adapted to any degree of accuracy that may best suit the particular case under consideration, and contracted methods of working are explained by means of which all superfluous figures may be omitted.

The book should prove very useful for many purposes, such as in mercantile calculations, the evaluation of convergent series, the compilation of tables, &c. Every care has been taken by both author and printer to make the tables thoroughly trustworthy, and to facilitate reference. They are printed in clear bold type, and the general arrangement is very attractive.

RECENT ENTOMOLOGICAL WORKS.

Monograph of the Coccidae of the British Isles. Vol. ii. By Robert Newstead. Pp. 270; pls. F., xxxv.–lxxv. (London: Ray Society, 1903.)

The Coccidae of Ceylon. By E. Ernest Green, F.E.S. Parts i.–iii. Pp. xliii+249; pls. i.–xciii. (London: Dulau and Co., 1896, 1899, 1904.)

New Zealand Neuroptera; a Popular Introduction to the Life-histories and Habits of May-Flies, Dragon-Flies, Caddis-Flies, and Allied Insects inhabiting New Zealand, including Notes on their Relation to Angling. By G. V. Hudson, F.E.S. Pp. ix+102; with eleven coloured plates. (London: West, Newman and Co., 1904.) Price 10s. 6*d.*

ENGLISH entomologists and horticulturists are to be congratulated on the completion of Mr. Newstead's important work, which furnishes us, for the first time, with a satisfactory account of the British species of one of the most destructive families of insects, the Coccidæ or scale insects. They are peculiarly destructive to trees and greenhouse plants,

though by no means exclusively attached to them, and are consequently very liable to be carried from one country to another. But it is rather startling to read in the preface,

"The number of species found within the British Isles is eighty-eight, with four varieties; of this total, fifty-one species and two varieties have been found living under glass, and have undoubtedly been introduced from other countries. A few of these aliens have, apparently, existed in this country as plant pests for more than half a century; while others have been introduced within the last fifteen years, and with the exception of a few species, have apparently come to stay, and add to the difficulties of plant-culture."

The males are small delicate insects, and the females are apterous, and are sometimes ornamented with elegant laminated appendages of wax, as in the species of Orthezia, which are not uncommon on grass, nettles, and other low plants. It must not be forgotten that although the Coccidæ include such destructive insects as the American blight and the San José scale, other species furnish us with some of the most useful products obtained from insects, such as cochineal, lac, &c. It remains to add that Mr. Newstead has given us a very full account of the transformations, habits, &c., of each of our British species, and that the plates are excellent.

There are few more useful, and at the same time few more injurious, families of insects than the Coccidæ, and also few which have been so much neglected by entomologists until within the last ten or fifteen years, though latterly they have been so much studied by good observers in most parts of the world that our knowledge on the subject has advanced by leaps and bounds. Thus, in 1891, only seven species of Coccidæ were recorded from Ceylon, but Mr. Green took up the study immediately afterwards, and in November, 1894, he was already able to enumerate not seven, but seventy-two distinct species which he had observed up to that date. In the preface to the present work, dated September, 1896, he says:—

"This large number will be almost doubled in the present work, . . . and when other parts of the island have been properly explored, it is probable that considerably over two hundred species will be recognised."

It is needless to say that such estimates usually prove to be very much below the mark. The three parts of Mr. Green's book already published include ninety-one species, belonging to three subfamilies out of eleven (Conchaspinæ, Diaspinæ, and Lecaniinæ, of which last only the genus Lecanium is at present monographed), and nine genera, besides preface, glossary of terms, introductory and supplementary chapters on habits, classification, remedial measures, &c. We are not told how many more parts will be required to complete the work, and it is possible that Mr. Green himself cannot at present decide, for there will no doubt be large additions required to the earlier portions. He appears to have done his work very completely and thoroughly, and the illustrations are excellent. Respecting these, Mr. Green writes:—

"The lithographic plates, reproduced from my own drawings, have been most carefully printed in colours by P. W. M. Trap, of Leiden."

We are pleased to see that Mr. Hudson is continuing his efforts to make the small, but highly interesting, insect fauna of New Zealand more widely known, and we hope he will continue to deal with other orders in succession. As in other groups of animals, the Neuroptera exhibit the usual characteristics of the fauna, a very small total number of species, a striking absence of most of the characteristic Australian groups, and the presence of a very few remarkable species peculiar to New Zealand. Among the latter we may mention the handsome dragon fly *Uropetala Carovei* (named by Adam White after the author of the "Story Without an End"), which superficially resembles our British *Cordulegaster annulatus*, Latr., but is larger.

Mr. Hudson describes the early stages of many of the species he notices, and figures several larvæ and pupæ in addition to the perfect insects. In an appendix he discusses the food of trout in New Zealand, founded on an examination of the contents (chiefly insects) of sixty trout stomachs. On the other hand, the larvæ of some of the larger Neuroptera may (like those of Dytiscus among the Coleoptera) be destructive to fish. Thus we read (p. 5), "The larva of *Stenoperla prasina*, Newm., might perhaps prove destructive to very young fish."

The Mallophaga and Psocidæ are not included in the present volume, and the Embiidæ and Panorpidæ are unrepresented in New Zealand. We have thought a comparison of the number of species of the families dealt with by Mr. Hudson, found in Britain and New Zealand respectively, might be interesting:—

Families	Britain	New Zealand
Termitidæ (White Ants)	0	3
Perlidæ (Stone Flies)	24	3
Odonata (Dragon Flies)	40	10
Ephemeridæ (May Flies)	37	13
Sialidæ (Alder Flies)	2	1
Hemerobiidæ (Lace-winged Flies)	48	8
Phryganeidæ (Caddis Flies)	136	24

W. F. K.

DARWINISM AND THE STATE.

La Concurrence sociale et les Devoirs sociaux. By J. L. de Lanessan. Pp. 308. (Paris: Félix Alcan, 1904.) Price 6 francs.

M. DE LANESSAN has added yet another to the many books that undertake to show the working of Darwinian principles among civilised races, and this, like so many other books dealing with the same subject, shows no real knowledge of Darwinism. The author is strongly anti-Darwinian, and maintains that the struggle for existence leads to degeneration in the labouring class, which finds itself over-matched in the struggle against an aristocracy or a plutocracy.

At the outset some clear definition is needed. What is meant by degeneracy? Apparently our author means the under-development of the individual through defective nourishment and unhealthy conditions generally. This is, no doubt, a great evil, but it is not racial degeneracy. Would M. de Lanessan deny that the physical strength of civilised peoples is maintained by the large amount of elimination that still goes on? (In England nearly 50 per cent. of the population die before the average age of marriage,

and so approximately that percentage is from the evolutionist's point of view, of no account.) The most thorough-going Darwinian would agree that a nation is weakened by class antagonism, just as a hive of bees would suffer if the workers were divided into two factions who were always thwarting one another. The struggle for existence often takes the form of a struggle between communities, not between individuals, and it scarcely needs to be said that one which is not distracted by disunion is stronger than one which is. Disunion within is a bad thing, but opposition from without may be a blessing. The constant presence of an enemy almost at the gates was the making of ancient Rome. M. de Lanessan owns that war, more than anything else, strengthens the bond of union among citizens and fosters the growth of patriotism. Indeed, without war national feeling would not have existed. Our author, after half admitting this, speaks of a supreme phase of evolution when there will be no distinction of races.

The second part of the book is more practical and more interesting. Anti-Darwinism disappears for a while, and we hear only of the duties of the State. Since unchecked competition, whether between classes or individuals, is disastrous, the State must limit and regulate it. The State must deal with questions of public health, inspect factories, and see that workmen are not exposed to unnecessary dangers and are compensated if injured. The State should see that distress is relieved. Old age pensions should be provided even for those who are too poor to contribute towards them themselves. But saving should be encouraged in every way, though our author owns that accumulations of capital lead men to choose the wrong women as wives. The State must make every effort to prevent war between capitalists and their employés. A long chapter is devoted to the progress of the race, no distinction being drawn between evolution and progress in civilisation. Mothers and their children must be better cared for. The length of the working day must be curtailed, since this would ennoble the lives of workmen, and so improve future generations. Education must be supplied gratis by the State, and should be of a practical kind, the subjects being such as will help a boy in after life. Science, not literature, is what is wanted. Finally, morality and religion come up for discussion. The State must instil moral principles and leave religion alone. Altogether the State has a great deal of work to do.

F. W. H.

CHEMISTRY OF THE SUGARS.

Die Chemie der Zuckerarten. By Prof. E. O. von Lippmann. Dritte Auflage. Two vols. Pp. xxxiii+2003. (Brunswick: Vieweg und Sohn, 1904.) Price 30 marks.

The appearance of a new edition of Prof. von Lippmann's well known treatise is of importance to all interested in the chemistry of the sugars. To workers in this field the book has long been indispensable and in daily use. The author is to be congratulated on the care and accuracy with which he has compiled the third edition. Since the appearance of the previous edition, in 1895, the work has almost doubled in size, owing to the very large amount of investigation which has been done in connection with the carbohydrates, especially on the physiological side. Two new chapters, dealing with formation in the plant and physiological behaviour of the sugars, have been appropriately introduced. The book preserves its former arrangement: under each sugar is given its occurrence, preparation, properties, estimation and a complete glossary of its derivatives, so that reference to any particular point is very easily made. Special chapters are devoted to constitution, configuration and synthesis and to the relationship between the physical constants of the various sugars. The book is clearly printed in large type and space formulæ are liberally used. The inclusion of investigations published early this year shows how completely the account has been brought up to date and reflects the greatest credit on author and printers alike.

It is easy, with the aid of such a work, to take stock of the progress made in sugar-chemistry during the last ten years, the second edition having been published shortly after Fischer's classic syntheses of the hexose sugars. To the eleven out of the possible sixteen aldohexoses, synthesised by this chemist, no new additions have been made, though the degradation methods of Wohl and Ruff have enabled us practically to complete the series of the inferior sugars—thus there are described two aldo- and one keto-trioses, four aldo- and one keto-tetroses and seven aldo- and four keto-pentoses, only one aldo-pentose, *l*-lyxose, remaining to be synthesised. But our shortcomings are also painfully evident. Although the series of the monosaccharides is almost complete but little progress has been made either in characterising or in determining the structure of the disaccharides; and from the synthesis of cane-sugar by purely chemical means we are seemingly as far off as ever. One natural biose—melibiose—however, does appear to have been obtained synthetically and the most recent work points to the possibility of synthesising biose sugars by means of enzymes, a process which must be closely allied to that taking place in nature. It is in this direction, in fact, that we have grounds to hope for the next great advance in our knowledge.

The relationship between configuration and susceptibility to the action of enzymes or to alcoholic ferments affords one of the most striking chapters in physiological chemistry. Thus the only fermentable sugars contain six carbon atoms—neither more nor less. The statement that glycerose syrup was fermentable has since been withdrawn and we believe also that the supposed fermentability of mannononose has been recognised as incorrect. Of the eleven known aldo-hexoses only three—glucose, mannose and galactose—and but one ketose—fructose—are fermentable. Not only do these fermentable hexoses occur naturally but three of them are so closely related that they possess a common enolic form; it is all the more remarkable that the closely related aldopentoses, arabinose and xylose, which are so abundant in nature, are not fermentable.

Regarding the work as a whole, it is beyond question that not only those interested in the carbohydrates but chemists generally owe Prof. Lippmann a great debt of gratitude for his labours.

OUR BOOK SHELF.

Religion and Science: Some Suggestions for the Study of the Relations Between Them. By P. N. Waggett, M.A. Pp. xii+174. (London: Longmans, Green and Co., 1904.) Price 2s. 6d. net.

It is pleasant to find in a book which seeks to deal from the religious standpoint with the relations between religion and science, a full and candid recognition of the claims of natural knowledge. The author of the present volume, whose qualities would no doubt have carried him far had he chosen the field of scientific research for the exercise of his chief activity, has not forgotten his early training. We should not expect from Father Waggett, nor do we find, the least attempt to blink or to minimise the results of scientific investigation in any department of learning. "Religion," as he says, "can have no possible interest in believing what is not true"; nor, it may be added, can religion afford to ignore what *is* true, from whatever quarter the demonstration of truth may arrive.

The book is not to be taken as a manual of apologetics—in fact many of those to whom it is primarily addressed may be inclined to complain of the author for not coming to closer quarters with the outstanding questions between religion and science. Its object is rather to state the present position, to suggest the lines on which future discussion should proceed, and to indicate the most hopeful means of arriving at a satisfactory conclusion, whether in the realm of thought or conduct. This object is carried out temperately and fairly, and with no lack of appreciation of what is strong in the scientific and philosophical position.

The author speaks, with possibly undue modesty, of his own opinions on the "domestic" issues that divide biologists. Holding, as he does, that "natural selection remains scientifically the most probable and philosophically the most welcome account of the adaptations of animal and vegetable life," he is perhaps inclined to attach too much weight to the arguments that have been brought forward by various scientific authorities on the other side. We miss any explicit reference to the views of Baldwin, Osborn and Lloyd Morgan, which have an important bearing on the whole question of adaptation, and go far towards removing some of the difficulties inherent in the rigid view of heredity. More stress might also have been laid on the quantitative aspect of variation, which is now taking definite shape in the hands of Karl Pearson and other workers. The book, however, on the whole is well abreast of modern inquiry, and may be studied with advantage by many others besides the class of readers for whom it is chiefly intended. F. A. D.

The Thompson-Yates and Johnston Laboratories Report. Vol. v. (New Series). Part ii. December, 1903. (Published for the University Press of Liverpool by Longmans, Green and Co.) Price 12s. 6d.

This new volume of the "Thompson-Yates and Johnston Laboratories Reports" opens with obituary notices of the Rev. Stephen Yates, to whose munificence the Thompson-Yates Laboratories owe their foundation, and of Prof. Nocard. The preliminary report of the trypanosoma expedition to Senegambia of the Liverpool School of Tropical Medicine occupies two-thirds of the volume, the authors being Mr. Dutton and Dr. Todd, to whom praise is due for the careful and detailed account of their journey and researches. (This has also been published as a separate report.) The laboratory methods of investigation are first described, and the results of the examination of a number of natives and of various animals for the presence of trypanosomata are then detailed. Only a small proportion of natives was found to be infected, and various experiments on the transmission and pathology of the trypanosoma are given at length. Horses were found to suffer from a fatal trypanosoma disease differing apparently in some respects from nagana. Trypanosomes were also detected in a number of birds, frogs, tortoise, mice, &c. The report is copiously illustrated, and forms an important contribution to the subject of trypanosomiasis, the appended bibliography being a very full one. Mr. Theobald adds notes on the species of mosquitoes collected in this expedition. Among these is a new species coming very near Stegomyia, for which a new genus is created, Catageiomyia. Prof. Ronald Ross contributes a brief article on a new human parasite, the Leishmann-Donovan body, which has already been referred to in these columns (Nature, vol. lxix. p. 495). Messrs. Glynn and Matthews give some interesting details of the numbers of bacteria and their variation under different conditions in swimming baths, and Dr. Stephens and Prof. Boyce detail the examination of a diseased haddock, with description of a parasite the nature of which is not clear. The general "get-up" of the volume maintains the standard of its predecessors, paper, printing, and illustrations all being excellent.

R. T. Hewlett.

L'Industrie de la Soude. By L. Guillet. Pp. 178. (Paris: Gauthier-Villars, n.d.) Price 3 francs.

This little book is a publication of the Encyclopédie Scientifique des Aide-Mémoire. It treats of the extraction of common salt, and the hydroxide and carbonates of sodium and of sodium peroxide, and within its compass it gives a fairly accurate account of the modern methods of manufacture of these articles. It is not obvious, however, for what class of readers the work is intended. It is too technical for ordinary people; indeed, most manuals of theoretical chemistry give quite as much information on these special subjects as is contained in this book. On the other hand, no technologist or person actually interested in the manufacture of these articles would rest satisfied with the extent and nature of the descriptive matter. There may, however, be persons to whom a book with a modicum of theory and a minimum of practice appeals.

Telephoto-Work. By G. H. Deller. Pp. 64. (London: Dawbarn and Ward, Ltd., 1904.) Price 1s. net.

This little book on telephoto work is one that will appeal to the numerous photographers who now keep a telephoto lens among their photographic equipment. The late author has described fully, illustrating his remarks with an excellent set of process reproductions, the many directions in which this lens may be successfully used, such as in landscape work, architecture, portraiture, and, finally, in short exposure work. Two other useful chapters, by H. Wild and H. M. Hames, deal respectively with the advantages of the "Adon" lens, and with an inexpensive means of practically learning the elements of telephotography by means of a home-made lens.

Buy English Acres. By C. F. Dowsett. Pp. 224. (Published by the Author, Winklebury, Basingstoke.) Price 3s. 6d. net.

This is not a book in the ordinary sense. It is a collection of miscellaneous arguments, extracts from books, and biographical notes, all intended to prove that pleasure and profit may be derived from the purchase of English land. The absence of any attempt at coherence or sustained economic discussion is atoned for, so far as possible, by the author's great earnestness. Apart from that, the book has no serious qualities.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Variation of Atmospheric Absorption.

REFERRING to a communication from me in NATURE of November 5, 1903 (vol. lxix. p. 5), to the effect that a definitely less amount of heat had been received at the earth's surface in the last years than in preceding ones, I would ask attention to an article published in June in the *Astrophysical Journal*, in which I have further indicated that the diminution of the heat received in 1903 may well have been due not only to an increased absorption in our own atmosphere, but in part to a real change in the solar emission, connected with a diminished transmissibility of the solar envelope.

Still more recently I have made further experiments, as yet unpublished, on changes in the transmissibility of the solar atmosphere. These experiments, made by the study of homogeneous rays from a large solar image formed by a horizontal telescope of 140 feet focus, are independent of changes in the earth's atmosphere, and have indicated that the absorption in the solar envelope has decreased within the last six months.

In agreement with this, independent computations of the total solar radiation through our own atmosphere (and so far less trustworthy than those just mentioned) tend to show that the radiation of the sun has somewhat increased during the same interval. I desire not to be understood as stating that these recent changes have undoubtedly occurred, but I feel that there is increasing probability of the confirmation of this result.

There is no novelty in the suggestion that there may be an increase or diminution of solar heat and light due to various causes, and since my earliest statement of the absorption of the solar atmosphere, in the *Comptes rendus* of the Paris Academy of Sciences for March 22, March 29, and September 6, 1875, the subject has, in fact, engaged my continued attention.

What I wish to remark now is that it is only in comparatively recent years that the gradual perfection of the bolometer and other apparatus is providing specific data which render it likely that such changes are now coming within our means of direct recognition.

In sum, the result of the most recent spectrobolometric observations is an increasing probability that the solar radiation itself varies in a degree appreciable to our present means of daily observation, and a strengthening of the belief I have elsewhere expressed that it probably varied through much larger ranges in the past, and may do so again in the future

It will be seen that I do not venture yet to assert without restriction conclusions like these, which, so far as they may be shown to be true, are not merely of abstract interest, but which in a utilitarian sense may be said to be of far-reaching concern; yet I think it time to ask more general attention to them. S. P. LANGLEY.

Smithsonian Astrophysical Observatory, June 20.

Use of Radium in Section Cutting.

EVERYONE who has to cut microtome-sections of material embedded in paraffin-wax is frequently troubled by the electrification of the sections. The electrification causes the sections to adhere to the microtome-knife and to fold on themselves instead of being pushed easily across the blade of the knife so as to form a smooth ribbon. The adhesion to the knife also renders the transference to the microslip difficult, and often leads to the breaking up of sections and consequent loss of continuity in the seriation. Further, even when successfully detached from the knife, the electrified sections are apt to fly about in such an erratic way that it is often a matter of difficulty to arrange them in an orderly manner on the slip.

These undesirable phenomena may be completely avoided by fixing a 5 mg. tube of radium bromide on the microtome-knife close to where the paraffin ribbon is forming. Apparently the radiations from the radium discharge the electrification of the paraffin sections by ionising the air in their neighbourhood. HENRY H. DIXON.

Botanical Laboratory, Trinity College, Dublin.

The Blondlot *n*-Rays.

THERE is reason to think that M. Blondlot has rendered very valuable service to science by directing the attention of physicists to the remarkable, if not altogether mysterious, class of phenomena with which he has recently had to deal.

There can be no doubt that the phenomena, strange as they may seem to be, which he and his colleagues have observed, whether appearances or realities, or, should I say, subjective or objective effects, still leave something that remains unexplained. Psycho-physiological phenomena are not the less interesting because they happen not to be *physical effects* as ordinarily understood, and if they can lead scores of trained physicists astray, they should be regarded as all the more important.

For one, I am unhappy in that I cannot merely not see the effects, but neither have I been fortunate enough to meet with anybody who, on severe cross-examination in the dark, did not satisfy me that the variations in brightness which he had observed were altogether subjective, and the result of imagination or fatigue, for expectation counts for a great deal in these observations, and concentration of attention for still more.

The one thing that seemed conclusive about these rays was that they produced so great an increase in the brightness of a small spark that the effect could be photographed, and M. Blondlot has himself shown us photographs which it would appear show unmistakably this result.

I have followed in his footsteps as closely as I could, but unfortunately have not obtained any difference in the photographic effects which could not be attributed to a spurious cause. In M. Blondlot's experiment there is no proof that the diminished brightness of the spark, when a lead screen is interposed, is not due to the presence of the metallic screen itself, which is so close to the spark that it would damp the oscillations of the spark and affect its photographic effect. I have preferred to put out the source of *n*-rays altogether, and to wait for some time, ten minutes or so, or to place a lead screen at a considerable distance from the spark.

I have used a spark of about 1/10th mm. between two brass spheres, each of about 1 cm. radius. The effect on a photographic plate 2 cm. away is that of a luminous band the edges of which are close to the spark, practically straight lines, and at a greater distance curve round, being branches of two hyperbolæ.

A change in the brightness of the spark is accompanied by a broadening of the band, and a change in the intensity of the diffuseness of the plate. The breadth of the band depends upon the exposure, and conversely upon the brightness of the spark. Except when there were errors in the adjustment of the apparatus, the two photographs taken on the same plate indicated the same brightness.

It is interesting to note in connection with this point that M. Jean Becquerel maintains that the alleged change in brightness of a phosphorescent screen is really due to an effect on the retina due to the *n*-rays which are reflected by the luminous body. This explanation, however, will not fit in with M. Blondlot's photographic effects, as these rays are not supposed to produce any direct photographic effects. But M. Becquerel's conclusion confirms my result that the *n*-rays, if there be any such, do not really intensify the brightness of a luminous body, even if this be the property by which they were supposed to have been discovered. JOHN BUTLER BURKE.

Cavendish Laboratory, June 21.

ABORIGINAL AMERICAN BASKETRY.[1]

THE attention of our readers has several times been directed to papers and memoirs by American students on aboriginal American basketry; some authors, like L. Farrand ("Basketry Designs of the Salish Indians," *Mem.* Am. Mus. Nat. Hist., ii., 5), G. T. Emmons ("The Basketry of the Tlingit," *l.c.* iii., 2), R. B. Dixon ("Basketry Designs of the Maidu Indians of California," *Am. Anthrop.*, June, 1900; "Basketry Designs of the Indians of Northern California," *Bull.* Am. Mus. Nat. Hist., xvii.), and a few others have studied the designs plaited in baskets, and have discovered their symbolism. W. H. Holmes ("A Study of the Textile Art in its Relation to the Development of Form and Ornament," Sixth Ann. Rept. Bureau Ethnol.) was one of the first to direct attention to the effect of the technique on the ornamentation of baskets, while the technique itself of basketry has persistently been studied by Dr. Otis T. Mason, and now he has increased the indebtedness of ethnologists to his labours by the publication of a monograph which gives a much needed general survey of aboriginal basketry in America.

As is usual in publications coming from the United States, this work is lavishly illustrated, there being 212 figures in the text and 248 beautiful plates, several of which are coloured. The memoir deals with basket

FIG. 1.—Pomo Basket-maker.

making (including a valuable section by F. V. Coville on the plants used in basketry), ornamentation and symbolism, uses of basketry, and ethnic varieties of baskets. The last section is the most valuable, as it enables us for the first time to make a comprehensive survey of this beautiful industry as practised by the aborigines of North America, for, despite its title, the basketry of Mexico and of Central and South America is only cursorily dealt with in this monograph.

Owing to differences of climate, rainfall, and other characteristics of environment, the materials for

FIG. 2.—Modified Forms on Basketry.

basketry vary greatly from region to region throughout America, and this in spite of all ethnic considerations. Again, the motives for the use of basketry differ from place to place, so much so that peoples of one blood make one ware in this place and another in that. Finally, however, writes Dr. Mason, it must never be forgotten that the ideas, utilitarian and artistic, in the minds of the manufacturers themselves, serve to bestow special marks upon the work of different tribes, so as to give to them ethnic or national significance in any circumstances. Were there no mixture of tribes it might be possible to state in every case the maker of each specimen from the technique and the ornamentation; but throughout the entire continent the practice of capturing women was common, and in each case the stolen ones carried to their homes the processes they had been familiar with in their native tribe, and, further, the materials for basketry were traded, as were probably the baskets themselves. New designs are occasionally introduced along with ancient patterns, as may be seen in Fig. 2, where dogs and horses are interspersed among pre-Columbian decoration; indeed, the influence of the white man is very rapidly modifying native American basketry; "in methods, forms and colours truly old things have passed away, and, behold, all things have become new." A. C. H.

THE MINING STATISTICS OF THE WORLD.

ONE of the recommendations of a Departmental Committee of 1894 was that the British mining industry should be compared with similar industries of other countries, and from that time Sir Clement Le Neve Foster compiled annually for the Home Office an invaluable collection of comparative mineral statistics. Every year the report showed improvement, and every year the difficulties arising from want of adequate official statistics were more nearly obviated. While the present report was in preparation Sir

Clement Le Neve Foster died, and it has therefore not had the advantage of his exceptional technical knowledge, literary skill, and critical acumen in its final revision. His loss to the Home Office is a serious one, and it will be difficult to find an editor with his wide acquaintance with foreign mining literature to fill his place.

The information given in the report deals with the number of persons employed, the quantity and value of minerals produced, and the loss of life from accidents in mines and quarries throughout the world. The statistics given in this concise, intelligible and inexpensive form are of the greatest importance from a commercial point of view. In the United Kingdom alone the value of the minerals produced in 1902, the year under review, was 107,104,884*l*., and the vast sums representing British capital invested in mines in all parts of the world will be readily appreciated. Some indication of the growth of the mining industry during recent years is indicated by the following comparison of the world's output of metals in 1889 and in 1902:—

	1889 Metric tons	1902 Metric tons
Iron	26,000,000	42,669,000
Gold	182	447
Silver	3,900	4,753
Copper	266,000	572,000
Lead	549,000	803,000
Zinc	335,000	503,000
Tin	55,000	93,000

In 1902 the world produced 803,157,000 tons of coal, 22,869,000 tons of petroleum, and 13,279,000 tons of salt. Of the coal supply, 34 per cent. was furnished by the United States, 29.5 per cent. by the United Kingdom, and 19.4 per cent. by Germany. Although the United States outstripped Great Britain in production, the value of the British product was 93,521,000*l*., whilst that of the American was 75,373,000*l*.

As gold producers, the British possessions take the first place, furnishing more than half the world's supply. Australia supplied 24 per cent., the Transvaal 12 per cent., and Canada 7 per cent. of the total. The United States contributed 27 per cent. The value of the total production exceeds 60,000,000*l*. Nearly one-fourth of the world's salt and three-fifths of the tin are produced by the British Empire. On the other hand, the production of copper, lead, petroleum, silver, and zinc is small in comparison with the world's output. Of copper, the United States, with the enormous output of 299,000 tons, produce more than half the copper of the world, and Spain and Portugal together about one-tenth. The United States also produce most lead, 30 per cent. of the world's total, Spain and Germany following. Russia and the United States are the two great petroleum producers. In the British Empire, Canada and Burma are the only oil regions, and their production is comparatively small. Of silver, the United States again are the largest producers, followed closely by Mexico. The German Empire, with its rich Silesian mines, is the leading zinc-producing country, furnishing one-third of the world's supply. The United States take second place in the list. Of other valuable minerals raised in 1902, diamonds to the value of 4,950,000*l*. were produced in Cape Colony. Italy has no equal for its sulphur (value 1,706,000*l*.), Chili for its nitrate of soda (value 9,500,000*l*.), Germany for its potassium salts (value 2,000,000*l*.), Spain for its mercury (value 173,000*l*.), and the United States for their phosphates (value 1,000,000*l*.).

Any strictly accurate comparison between the number of persons employed in the mining industries of the various countries is impossible. The figures collected are, however, sufficient to give a general idea of the relative importance of mining in each country. The total number of persons engaged in mining and quarrying throughout the world may be taken at 4,500,000, of whom one-fifth are employed in the United Kingdom and one-third in the British Empire. More than half the total number were employed in mining coal, Great Britain employing 750,000, the United States and Germany each 500,000, France 165,000, Belgium 135,000, Austria 123,000, and India 100,000.

The accident statistics are not so complete as might be wished. For coal mines, the figures show that the death rate from accidents in mines and quarries per 1000 persons employed is 1.24 in the United Kingdom, 1.46 in the British Empire, 1.09 in France, 1.93 in Germany, and 3.25 in the United States. The death rate for foreign countries generally is 2.20. It is evident that mining is conducted in Great Britain with a far smaller risk of accident to the workers than in most other countries.

The first part of the general report on mines and quarries for 1903 has also been issued. It contains statistics of the number of persons employed, the output of minerals, and the number of accidents in the United Kingdom. The British production in 1903 included 230,334,469 tons of coal, 16,198,021 tons of clays and shale, and 13,715,645 tons of iron ore.

B. H. B.

NOTES.

IN the long list of birthday honours published on Friday last, we notice that Mr. Charles Booth, F.R.S., has been made a Privy Councillor; and that the honour of knighthood has been conferred upon Prof. J. Dewar, F.R.S., and Dr. T. Stevenson, scientific analyst to the Home Office. The Colonial Office list includes the name of Prof. W. Baldwin Spencer, F.R.S., who has been appointed a Companion of the Order of Saint Michael and Saint George (C.M.G.).

H.R.H. PRINCESS HENRY OF BATTENBERG will privately inaugurate the annual exhibition of the Beni Hasan excavations committee at the rooms of the Society of Antiquaries in Burlington House. The exhibits include the antiquities discovered at Beni Hasan and Negada by Mr. John Garstang, reader in Egyptian archæology in the University of Liverpool, and paintings by Mr. Harold Jones, artist to the expedition. The exhibition will be open from July 8–23 inclusive.

THE French Society of Civil Engineers has this year awarded its prizes as follows:—the annual prize to M. J. Bernard for his work on the installation in the Red Sea of three lighthouses in circumstances of especial difficulty. The Michel Alcan prize was awarded to M. L. Guillet for his researches on the composition of steel, and the F. Coignet prize went to M. V. Picou for his work on the regulation of dynamos. A prize was awarded to Prof. E. Hospitalier for his works on the study of phenomena which by their rapidity and frequency baffle ordinary methods of analysis.

H.R.H. THE PRINCE OF WALES has consented to become patron of the Royal Meteorological Society.

THE twenty-second congress of the Sanitary Institute will be held in Glasgow from July 25–30, under the presidency of Lord Blythswood. Sir Richard Douglas Powell, Bart., K.C.V.O., will deliver the lecture to the congress on "The Prevention of Consumption." It appears from the programme that 250 authorities, including several county

councils and county boroughs, have already appointed delegates to the congress, and as there are more than 3300 members and associates in the institute, there will probably be a large attendance in addition to the local members. In connection with the congress, a health exhibition of apparatus and appliances relating to health and domestic use will be held as practical illustration of the application and carrying out of the principles and methods discussed at the meetings. Popular lectures will be given in the exhibition on physical development, by Dr. P. Boobbyer; care of eyesight, by Dr. James Kerr; care of the teeth, by Mr. G. Cunningham; feeding and digestion, by Prof. A. Bostock Hill; and healthy houses, by Prof. H. R. Kenwood. The sections and their presidents are:—(1) Sanitary science and preventive medicine, Prof. J. Glaister; (2) engineering and architecture, Prof. H. Robinson; (3) physics, chemistry, and biology, Prof. Frank Clowes. There will be eight special conferences, the subjects and presidents of which will be as follows:—Municipal representatives, Mr. W. F. Anderson; industrial hygiene, Mr. J. Steele; medical officers of health, Sir C. A. Cameron, C.B.; engineers and surveyors to county and other sanitary authorities, Mr. W. Weaver; veterinary inspectors, Prof. James McCall; sanitary inspectors, Mr. T. F. Strutt; women on hygiene, the Duchess of Montrose; the hygiene of school life, Prof. John Edgar.

The death is announced of Lieut.-General Dubrovin, who was for a long time secretary of the Imperial Academy of Sciences at St. Petersburg.

Prof. W. Kaufmann, of Bonn, has been awarded the Von Baumgartner prize of the Vienna Academy.

Prof. van 't Hoff has been appointed honorary director of the medical faculty of Utrecht, and the newly erected chemical laboratory there has been named the Van 't Hoff Laboratory in his honour.

The Imperial Academy of Sciences of Vienna announces the following grants:—To the Vienna Society for Solar Observation, 1600 krone for observations on climatic changes in the Goldberg glacier, and to Prof. Ritter Beck von Managetta (Prague) 600 krone for studies of plant distribution in the Julian Alps. From the Wedl bequest, to Drs. Obermayer and Pick (Vienna) 600 krone for the chemistry of immune substances, to Dr. Moritz Probst 800 krone for continuation of work on the brain, to Dr. Karl Camillo Schneider 400 krone for a zoological expedition to Grado, to Prof. Julius Tandler 1000 krone for studies in the development of birds. The committee of the Treitel legacy awards the following grants:—To Prof. Hans Skraup (Graz) 1500 krone for studies on albumens, to Dr. Franz Werner 6000 krone for a zoological expedition to the Egyptian Soudan, to Prof. Julius Wiesner 4000 krone for effects of light on plant life in the Yellowstone district, to the Austrian Meteorological Society 4000 krone for investigations of the upper atmosphere, and to the Earthquake Commission 5465 krone 39 heller.

That the depopulation of rural districts is a social problem of the times in France no less than in this country is evident from the report presented by Dr. A. F. Plicque to the *Bulletin de la Société d'Encouragement* for April. The author makes a special study of the conditions prevailing in the canton of Donnemarie-en-Montois (Seine et Marne). This canton is situated in the midst of a fertile agricultural district possessing an excellent climate, and within moderate distance of Paris, and from 1869 to 1891 there was a falling off in the population of from 9764 to 7683 inhabitants. It is also noteworthy that an inquiry in 1893 in the same district showed that 63 per cent. of the farm labour was imported from outside, and that without this imported labour agriculture in this fertile region would come to a standstill. The author traces the causes of the depopulation to ignorance of sanitary precautions leading to a high rate of infant mortality, emigration of young people to towns, effects of conscription, alcoholism, &c., and he considers the remedy to consist in improvements in primary and technical education, which should, in his opinion, "not merely give the child verbal forms, devoid of ideas, which he cannot understand, but should give children of rural communities an instruction suited to the surroundings in which they ought to live, and should develop, from their earliest years, a taste for agriculture." M. Plicque instances the success of this method in Belgium. In other words, the successful and contented ploughboy should not be encouraged to leave his plough in order to become an unsuccessful and discontented teacher.

Would life be possible if the nitrogen of the atmosphere were replaced by hydrogen? This is a question discussed by Regnault and Reiset, who gave an affirmative answer in their well known treatise on respiration. A fresh investigation of the question is now given by Dr. Arturo Marcacci in the Lombardy *Rendiconti*, xxxvii., 9, whose experiments were conducted at Palermo. The author found that animals introduced into such an atmosphere soon died, the symptoms all indicating that the death was due to cold, caused by the high thermal conductivity of the hydrogen. Another phenomenon was the marked increase in the absorption of oxygen and evolution of carbonic anhydride.

In 1902 the *Zeitschrift fur Krystallographie und Mineralogie*, founded by Prof. P. Groth, completed the twenty-fifth year of its publication. Many mineralogists in various countries felt the occasion provided a fitting opportunity to commemorate the services rendered to mineralogy and crystallography by Prof. Groth by initiating and editing that journal. Profs. M. H. N. Story-Maskelyne, W. J. Lewis, H. A. Miers, and Mr. L. Fletcher formed themselves into a committee, and in response to an appeal a sufficient sum of money was obtained to secure the services of Prof. E. Grützner, of Munich, to paint a portrait of Prof. Groth. The picture was formally presented to Prof. Groth on April 30 last, and was accompanied by a letter from Prof. Story-Maskelyne expressing the appreciation of Prof. Groth's work on the part of the subscribers. A photogravure of the portrait, executed by Dr. E. Albert and Co., of Munich, and a statement of receipts and expenses, will be forwarded shortly to each subscriber to the testimonial.

A new scheme for a North Polar expedition was described by M. Charles Bénard at a meeting of about fifty men of science held in the house of the Prince of Monaco, in Paris, on June 19. According to the Paris correspondent of the *Times*, M. Bénard explained at length why the only feasible and rational route of penetration of the Polar Sea was one a little north of that followed by the *Fram*. The expedition ought to start from a Norwegian port, cross the southern portion of Barents Sea, take in dogs at Karabora, coast along Yalmal, ship its coal at Port Dickson, transported thither by special steamer, pass at the end of the summer along the Peninsula of Taimyr, arrive by the end of the autumn at the islands of New Siberia, and then, instead of going northward, as did the *Fram*, manage at all costs, even if it be necessary to winter in the Liakhoff or Bennett Islands, to reach a point on the 150th degree of east longitude. Thence the ship or ships need only drift with the

ice. M. Bénard urges the utility of having the expedition composed of two vessels in touch with each other by means of wireless telegraphy. The expedition should take three years, but be provisioned for five. It would not cost more than 1,500,000 francs (60,000*l*.). The assembled company signed a memorandum declaring this expedition to be of scientific utility.

At a recent meeting of the Royal Photographic Society, Mr. Conrad Beck described the unofocal (or unifocal) photographic objective which has been worked out by Dr. Steinheil, of Munich. The principle of the new construction consists in the employment of positive and negative lenses all of which have the same focal length and the same mean index of refraction, thus overcoming the difficulty of satisfying the "Petzval condition." A positive focus is obtained by separating the positive and negative elements. An example with a maximum aperture of $f/4 \cdot 5$ appears at first sight like a symmetrical triplet consisting of three single lenses, with the central negative lens divided to allow space for the diaphragm. But the inner faces of the two negative lenses are concave to each other. In the series with an aperture of $f/6$, there is a greater space between the negative elements, each of which is much nearer to the outer positive component that it is more immediately associated with. Mr. Beck stated that even the $f/4 \cdot 5$ lens gives telescopic central definition, perfect freedom from distortion and flare, and a flat field of 60° well corrected for astigmatism. An incidental advantage of the construction is that it gives a more even illumination, as oblique beams are transmitted more fully than when the elements of the combinations are in contact.

The Paris correspondent of the *Times* states that M. Henri de la Vaulx is now completing his preparations for a third Mediterranean cruise in a specially constructed balloon, some particulars of which were given at Monday's sitting of the Academy of Sciences. M. de la Vaulx will employ a 20-horse power engine of the automobile type, attached to the car, which will work an aluminium screw seven metres in diameter.

A correspondent informs us that the optical illusion mentioned in Nature of June 2 (p. 107) is described in the *Proceedings* of the Royal Society of Edinburgh (vol. x., 1878–9). In the experiments described in that paper circular rotating discs, and also travelling bands of paper, were used for exciting the eye, and it is shown that whatever the nature of the motion impressed on the eye, the surface afterwards looked at appears to move in the opposite direction. If a rapidly flowing stream, for instance, be looked at steadily for a time, and the eye afterwards directed to the bank, part of the bank will seem to flow through the middle of the field of view. The image of the part of the bank that falls on the part of the retina affected by the image of the moving water seems to flow slowly in a direction contrary to that of the stream, causing that part of the solid earth to appear as if it had become plastic.

We have received from M. A. Lancaster the *Annuaire Météorologique* of the Royal Observatory of Belgium for 1904. For sixty-eight years the observatory published annals devoted to astronomy and meteorology combined, but since 1901 each science has been dealt with separately. The work consists of some 660 pages, and, in addition to monthly and seasonal meteorological data for various places, contains some valuable papers by M. Lancaster and others connected with the service, including the motions of cirrus clouds, and the dispersion of hail clouds, by M. Vanderlinden. The latter subject is still a controversial matter, and although the results hitherto attained by shooting and other methods are not generally considered satisfactory, the experiments are likely to be continued for some years.

The *Transactions* of the South African Philosophical Society (vol. xv., part i.) contain an important paper by Mr. J. R. Sutton on South African rainfall, being the fifth of a valuable series of studies on meteorological subjects which have appeared in the same publication. The tables exhibit the daily and monthly rainfall at Kimberley recorded by Mr. F. W. Matthews between 1877 and 1902, together with the diurnal variation and other useful details; also the monthly and annual rainfall at a large number of selected stations. The values relating to Kimberley have been discussed statistically and by the process of harmonic analysis. The yearly falls from Mr. Matthews's series vary from 9·34 inches in 1878 to 31·30 inches in 1891. The greatest average annual fall occurs at Maclear's Beacon, on Table Mountain (86·81 inches), and the least at Port Nolloth (2·46 inches). Speaking of the Kimberley values, Mr. Sutton states that March is the wettest and July the driest month, the increase or decrease from one to the other being gradual. Referring to South African rainfall generally, outside the Cape Peninsula and west coast, the author concludes that rainfall decreases on the whole with distance from the coast, and that it occurs with a high barometric pressure at Durban and a low pressure at Kimberley; it comes chiefly with south-westerly winds at the former station and with north-easterly winds at the latter. The principal barometric disturbances come from the south.

A small brochure, in which Mr. G. M. Woodrow treats of the cultivation and varieties of the mango, "the choicest fruit of Hindustan," has been published by Mr. Alexander Gardner, of Paisley, and can be obtained from the office of the *Gardener's Chronicle* and certain agents in India.

In the matter of floral variation, several of the violets offer an attractive field of study, and a paper by Mr. C. E. Britton dealing with floral variations among Surrey violets will be found in the *Journal of Botany* (May). The most important aberrations occur in the corolla, where, in the case of *Viola hirta*, all stages, from the normal single-spurred petal to the symmetrical condition of five-spurred petals, were observed. The condition of regular symmetry in the case of *Viola Riviniana* appears to be produced by the suppression of the spur, but the petals are all slightly pouched at the base.

The principal historical events and appointments connected with the Royal Botanic Gardens, Ceylon, are summarised by Mr. J. C. Willis in No. 10, vol. ii., of the *Agricultural Journal*. The expansion of the gardens has not only included the formation of five branch institutions situated in different climatic regions of the island, but during the term of office of the present director the scientific staff has been increased by the appointment of several specialists. Although the introduction and investigation of plants of economic value have been carried out in Ceylon since the institution of the gardens in 1860, there has been a gradual change in the scope of the work, and systematic collection and identification have given place to physiological research and experimental cultivation.

The skull of the dinosaur *Triceratops serratus* is described by Dr. R. S. Lull (*Bull. Amer. Mus. Nat. Hist.*, xix.). A figure of the palatal aspect shows the extreme length to be about 6 feet 4 inches.

In the *Ottawa Naturalist* for May, Mr. L. M. Lambe describes the phalanges of the manus of *Ornithomimus altus*, which evidently had long and sharp claws. He considers that this dinosaur was capable of rapid motion in pursuit of prey, and had the power of tenaciously grasping with its fore limbs.

To vol. xv., part ii., of the *Proceedings* of the Royal Physical Society of Edinburgh, Mr. N. Annandale communicates the first instalment of a series of papers on the zoology of the Færöes, dealing in this instance with the land and fresh-water molluscs, isopods, and insects, each group being treated by a specialist.

From the Field Columbian Museum we have received publications of the geological series, vol. ii. In No. 3 Dr. S. W. Williston gives a detailed description of the skeleton of the American pterosaur *Nyctosaurus gracilis*, which was formerly regarded as Pteranodon, and in No. 4 Mr. E. S. Riggs gives a description and restoration of the dinosaur Apatosaurus (formerly Brontosaurus). Mr. Riggs remarks that there is a striking similarity between his figure and the original restoration of the genus by Marsh. Later on Marsh, evidently dissatisfied with its proportions, inserted additional vertebræ and ribs, and otherwise modified the skeleton, almost to the extent now rectified by the evidence since acquired.

The whole of the seven articles in the first part of vol. vi. of the *Bulletin* of the College of Agriculture at Tokyo University are from the pen of Prof. C. Sasaki, all but one dealing with insects of commercial value, more especially silk-producing moths. Special interest attaches to the description, illustrated with two coloured plates of the adult insect and larva, of native methods of rearing the fine Yamamai moth (*Antheroea yamamai*). Five of the other papers treat of various races of silkworms and different modes of feeding them, while the sixth is devoted to the life-history of the wax-producing coccid *Ericerus pela*. In the eighth and last paper the author describes a new field-mouse, under the name of *Arvicola hatenedzumi*, which appears to be the Japanese representative of *A.* (or *Microtus*) *subterraneus*.

A number of experiments have been carried out by Konradi on the duration of life of pathogenic bacteria in water (*Centr. f. Bakt.*, xxxvi., No. 2, p. 203). These show that the anthrax bacillus, the *Micrococcus pyogenes aureus*, and the typhoid bacillus may ultimately displace the ordinary bacterial forms of water and survive for a long period, anthrax for 3½ years, the *M. aureus* for as long as 545 days, and the typhoid bacillus for more than 500 days, their pathogenic properties still being retained.

Prof. Lingard raises the question whether the *Piroplasma bigeminum*, the parasite of Texas fever of cattle, can find a habitat in the human subject (*Centr. f. Bakt.*, xxxvi., No. 2, p. 214). He describes a case in which a native cattle attendant staying near bovines, the subjects of Texas fever, developed an illness partly malarial, but partly, perhaps, due to infection with the Piroplasma, the special symptoms being continued remittent fever unaffected by quinine, hæmoglobinuria, and the presence in the blood of parasites similar to the Piroplasma.

Prof. Grindley and Mr. Mojonnier, of the United States Department of Agriculture, have published the results of experiments on the losses occurring during the cooking of meat (*Bulletin* No. 141). The chief loss in weight during the boiling, sautéing, and panbroiling (cooking in frying pan without fat) of meats is due to removal of water. In the roasting of meats, the loss is due to both water and fat. When beef is cooked in water, 3·25–12·67 per cent. of nitrogenous matter, 0·6–37·4 per cent. of fat, and 20·0–67·4 per cent. of mineral matter of the uncooked meat are found in the broth. In roast meat the loss is much less, 0·25–4·5 per cent. of the nitrogenous matter, 4·5–57·5 per cent. of the fat, and 2·47–27·2 per cent. of the mineral matter being found in the dripping. As a rule, the larger the piece of meat cooked by boiling or roasting, the smaller is the relative loss. Panbroiling seems to be the mode of cooking that occasions the least loss. A statement which will cause surprise to some is that beef which has been used for the preparation of beef-tea or broth has lost comparatively little in nutritive value, though much of the flavouring material has been removed.

The Geological Survey in Ireland has just issued a memoir on the geology of the country around Belfast, with a specially prepared one-inch map of the district colour-printed to show the various drift deposits and solid strata where these appear at the surface. On the margin of the map are engraved and coloured two longitudinal sections to explain the general structure of the country—a useful feature, which serves to render this excellent map more intelligible to the uninitiated. The memoir and map are the work of Messrs. G. W. Lamplugh, J. R. Kilroe, A. McHenry, H. J. Seymour, W. B. Wright, and H. B. Muff. The description of the older rocks, from the Ordovician (or Lower Silurian) series to the Tertiary basalts, is based largely on the previous work of the Survey, supplemented by the information published by private workers. The drifts, on which the field-staff was specially engaged, are very fully described, and in the explanation of their mode of origin reasons are given for rejecting the marine theory and for adopting the land-ice theory. There is much, however, of practical as well as of scientific interest in this volume; agricultural geology is especially dealt with, and there are notes on water supply, house sites, building materials, &c., records of deep borings, petrographical notes on the igneous rocks, and a bibliography.

It may be said that the Austrian Empire covers a wide field; but its manifold activity in matters of geological research is none the less remarkable. Among recent memoirs received by us are two by Dr. W. Teisseyre on the north-eastern foreland of the Karpathians (*Verhandlungen der k.k. geol. Reichsanstalt*, 1903, pp. 289–308, and *Beiträge zur Paläontologie und Geologie Österreich-Ungarns*, Bd. xv., 1903, pp. 101–126). In these the author traces the influence of older movements, and of the resulting crust-blocks, on the present structure of the Podolian lands, and seeks to reconstruct the country as it was, firstly, at the time of the Cenomanian marine transgression, and, secondly, at the opening of the Miocene period. In so doing, he is led to regard an anticlinal mass in Podolia, upheaved in Upper Jurassic times, as a somewhat belated offshoot of the Triassic folds of the Sudetic. Dr. Tietze's report on the work done by the Geologische Reichsanstalt in 1903 (*Verhandlungen*, 1904, pp. 1–44) describes the distribution of the field-surveyors, and the visits undertaken to other lands. Among the papers issued under his energetic guidance in 1903, we note F. Kerner's description of the "Fenster," or pseudo-inliers, of the Mosor Planina, where little patches of Eocene Flysch appear in the floor of hollows excavated naturally through Cretaceous limestone. Other evidence is forthcoming to show that the latter series has been thrust over the former. W. Hammer

(*Verhandl.*, 1903, p. 345) contributes a valuable paper on pegmatites in the Ortler Alps, in which he opposes the still popular view that such veins have been formed by lateral segregation from the surrounding rocks. Dr. Romberg (p. 365) adds yet another paper to the discussion of the inter-relations of the Monzoni rocks, in which he tilts vigorously against Dr. Doelter and his associated champions.

A TENTH edition of Mr. A. Jamieson's "Elementary Manual on Steam and the Steam Engine" has been published by Messrs. Charles Griffin and Co., Ltd.

MARCONI's Wireless Telegraph Company, Ltd., has published a catalogue dealing with Röntgen ray and high-frequency apparatus, instruments and accessories. The pamphlet, which is well illustrated, contains numerous useful hints as to the use of induction coils and the charging of batteries. Particulars as to the cost of instruments described are conveniently arranged, and the catalogue should be of service to workers in these branches of science.

WE have received a copy of the *Bulletin* for November, 1903, published by the Permanent International Council for the Exploration of the Sea, the contents of the first part of which were described in the issue of NATURE for June 9, p. 139. The present *Bulletin* is divided into four parts, dealing respectively with the following subjects:—the condition of the atmosphere and of the surface water; the temperature and salinity at various depths expressed in metres; the nitrogen, oxygen, and carbonic acid dissolved in sea-water; plankton tables for Finland, Sweden, Denmark, Germany, Holland, Belgium, England, Scotland, and Russia. Attached to the several parts are numerous charts showing the results arrived at by observers of different countries. The *Bulletin* may be procured from MM. Andr. Fred. Høst et Fils, of Copenhagen.

THE April number of the *American Journal of Psychology* contains a paper by Mr. C. Spearman entitled "'General Intelligence' Objectively Determined and Measured." By means of statistical methods of considerable refinement and elaboration, the writer claims to have proved that an absolute correspondence exists between the degree of general intelligence and general power of sensory discrimination, and that there is a variable correspondence between the latter and the more complicated intellectual activities of practical life. He believes in an underlying universal unity of the intellectual function, the psychical nature of which is to be discussed in a later paper.

THE second part of the first volume of the *British Journal of Psychology* was issued on June 10. It contains four papers and the proceedings of the Psychological Society. Dr. C. S. Myers writes on the taste-names of primitive peoples, and refers to the results of a few experiments he made with Dr. Seligmann in the islands of the Torres Straits. He found that the literal meaning of the phrase commonly used in the Torres Straits to denote sweetness is "tasting good"; that the same phrase is applicable to denote saltness, the usual word for which is derived from sea-water; the taste-names for salt and sour tend to be confused; and there is no specific name for the bitter taste. Precisely similar features are found when the taste-names of Indo-Germanic languages are examined. Dr. Myers extends his inquiry to other primitive peoples, and the results are given in his paper. Mr. W. H. Winch has a paper on immediate memory in school children. Prof. R. Latta contributes notes on a case of successful operation for congenital cataract in an adult, and Prof. W. McDougall deals with the variation of the intensity of visual sensation with the duration of the stimulus.

A VERY readable paper on radium, by Mr. E. P. Poulton, is contained in the March issue of the *Transactions* of the Oxford University Junior Scientific Club.

WE have received *Communications* No. 87 and No. 88 from the physical laboratory of the University of Leyden. In the first of these Dr. Kamerlingh Onnes describes the methyl chloride circulation used in the cryogenic laboratory, and in the second the results of the determination of the isothermals of mixtures of oxygen and carbon dioxide by Dr. W. H. Keesom are given.

IT is well known that the extension of the theory of the asymmetric carbon atom by Wislicenus to account for the isomeric relationships of ethylene derivatives is in many cases unable to explain observed experimental facts. In the current number of the *Zeitschrift für physikalische Chemie*, vol. xlviii. p. 40, Dr. Pfeiffer shows how it is possible to account for many of these observations by a modification of the van 't Hoff-Wislicenus theory. With this modification the formation of the *cis-* or *trans*-isomer can be predicted, whether the ethylene compound is obtained from an ethane or an acetylene compound.

THE Carnegie Institute of Washington has just issued a pamphlet (No. 7) containing an account of a new method for determining compressibility by Messrs. T. W. Richards and W. N. Stull. Bromine, iodine, carbon tetrachloride, chloroform, bromoform, water, and mercury have been examined. In the case of a substance like bromine, the liquid is hermetically enclosed in a very thin, flexible glass bulb, and subjected to compression under mercury, correction being made for the change in volume of the mercury and the glass. A new form of high pressure manometer is described the working of which depends upon the difference between the compressibility of water and mercury.

IN a recent experimental investigation by Dr. T. Wulf, published in the *Zeitschrift für physikalische Chemie* (vol. xlviii. p. 87), it is shown that the electromotive force at which hydrogen ions are liberated from solution, when determined galvanometrically, is quite independent of the pressure when this is varied between 0·01 and 800 atmospheres. On the other hand, the polarisation of the hydrogen electrode increases with the pressure, and this increase is in quantitative agreement with Helmholtz's formula. The experiments show very clearly that the passage of a current through the solution is not necessarily accompanied by the liberation of the gas in the form of bubbles.

THE question as to whether the so-called colloidal or pseudo-solutions are essentially different in character from ordinary solutions has been the subject of much discussion and experimental investigation of late years. By applying the optical method of Tyndall to solutions, Messrs. Lobry de Bruyn and Wolff, in the *Recueil des Travaux chimiques de Pays-Bas*, vol. xxiii. p. 218, arrive at the conclusion that there is no sharp line of demarcation between ordinary solutions and pseudo-solutions. Solutions of bodies of high molecular weight, such as tristearine and the hexabenzoyl derivatives of mannite and dulcite in methyl alcohol, chloroform and acetic ether, exhibit optical properties of the same nature as colloidal solutions. Light is reflected laterally from a beam incident on the solution, and this reflected light is polarised.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN JULY:—

July 2. 11h. 7m. Minimum of Algol (β Persei).
6. 13h. Conjunction of Jupiter and Moon. Jupiter 1° 49′ N.
9. 13h. 24m. to 13h. 44m. Moon occults 71 Tauri (mag. 4·6).
,, 14h. 5m. to 14h. 58m. Moon occults θ^1 Tauri (mag. 3·9).
,, 14h. 12m. to 15h. 0m. Moon occults θ^2 Tauri (mag. 3·6)
,, 17h. 31m. to 18h. 24m. Moon occults α Tauri (mag. 1·1).
11. 11h. 34m. to 13h. 28m. Transit of Jupiter's Sat. III. (Ganymede).
15. Venus. Illuminated portion of disc = 0·999, of Mars = 0·995.
18. 15h. 41m. Transit (ingress) of Jupiter's Sat. III. (Ganymede).
25. 9h. 38m. Minimum of Algol (β Persei).
27. Ceres stationary 3½° S. of α Scorpii (Antares).
28. Saturn. Major axis outer ring = 43″·33. Minor axis = 10″·87.
28–30. Epoch of Aquarid meteoric shower (Radiant 339° − 11°).

SMITHSONIAN INSTITUTION 1900 ECLIPSE RESULTS.—No. 1439 of the *Publications* of the Smithsonian Institution is devoted to a splendidly illustrated account of the equipment and work of the expedition sent out by the Astrophysical Observatory, under the superintendence of Prof. Langley, to observe the total solar eclipse of May, 1900.

In chapter i. the director, who was aided throughout by Mr. C. G. Abbot, gives a concise account of the objects of, and the preparations for, the expedition. Chapter ii. describes the establishment of the eclipse camp at Wadesboro, North Carolina, on the same field as the Yerkes expedition under Prof. Hale.

The loan of a 12-inch lens of 135 feet focal length by Prof. Pickering made the photography of the inner corona one of the most important objects. In summarising the results in chapter iii., Prof. Langley notes, among other things, that large prominences were observed, and appeared to be associated with regions of coronal disturbance. Bolometric observations of the inner corona showed that the heating power of its radiations was unexpectedly small. The search for an intramercurial planet was made with a camera of 3 inches aperture and 11 feet focus, and several suspicious images appeared on the plate, but as there was no confirmatory second photograph the results were inconclusive. Prof. Langley recommends a similar instrument for future observers.

The twenty-two beautiful plates which accompany the report display photographs of the observers and their instruments as erected, the corona, and parts of the inner corona.

THE ORBIT OF THE COMPANION TO SIRIUS.—From a discussion of numerous observations of its position angle and distance, Herr O. Lohse, of Potsdam, has determined the following elements (for 1900·0) for the orbit of the small companion to Sirius:—

T = 1894·337 (1844·956)	☊ = 44°·12
U = 50·381	i = 39°·91
n = −7°·14559	∞ = 212°·20
e = 0·598	a = 7″·427

A comparison of the observed places with those calculated from the elements, for various dates since 1862, shows that the elements are fairly correct, the mean error in position angle being generally less than 1°, and in distance less than 0″·2.

An ephemeris, for the years 1900–1912 inclusive, calculated from these elements, gives the position angle at the commencement of the present year as 116°·2, and the distance as 6″·6. Observations made at Yerkes on October 19 and 26, 1903, gave 115°·97, 6″·31, and 115°·06, 6″·33, as the respective position angles and distances for those dates (*Astronomische Nachrichten*, No. 3955).

OBSERVATIONS OF JUPITER DURING 1903.—The results of numerous observations of Jupiter which were made at Juvisy during 1903 are published and discussed by MM. Flammarion and Benoit in the *Bulletin de la Société astronomique de France* for June. From these observations, which agree with those of other observers, it appears that the northern equatorial band progressively diminished during 1903, appearing to condense towards the southern edge. The southern equatorial band appeared to be the centre of great activity, the great red spot forming a marked depression in the band, although not so sharply defined as in past years.

Several large bright spots appeared in the southern tropical zone, two of which, situated in longitudes 180° and 225° respectively, were remarkable. In the southern temperate zone several small white spots were observed which seemed to detach from the southern temperate band a quantity of the material of which the latter is composed. Summarising the observed phenomena, it is obvious that the southern hemisphere of Jupiter is in an active state of disturbance, whilst the northern hemisphere is remarkably quiescent.

OBSERVATIONS OF THE SATELLITES OF SATURN.—In the *Bulletin de la Société astronomique de France* for June, M. Lucien Rudaux publishes the results of a series of observations of five of Saturn's satellites made by him during the years 1892–7 and 1901–3 at his observatory at Donville (Manche).

His particular object was to record the changes in the brightness of each satellite, and from his numerous observations he concludes (1) that the satellites have periods of rotation equal to their respective periods of revolution; (2) that they (especially Japetus) have dark spots, probably permanent configurations, which cause a decrease in the satellite's apparent magnitude when presented to us; (3) consequently the apparent magnitude of each satellite varies periodically with the satellite's position in its orbit. These conclusions are certainly justified by the observations of Titan and Japetus, but in the case of Rhea the result is as yet uncertain.

THE GERMAN ROYAL NAVAL OBSERVATORY.—A quarto volume published by the German Naval Observatory under the general title "Aus dem Archiv der deutschen Seewarte" (twenty-sixth annual publication, 1903) contains papers on the following subjects:—(1) On the calculation of lunar distances by the aid of the Mercator functions; (2) estimation of the latitude of Heidelberg Observatory and its variations; (3) the daily variation of the magnetic declination; (4) the wind variation on the German coast; (5) on the "going" of the standard clocks of the German Naval Observatory; (6) the definitive elements of comet 1887 II. (Brooks). In the last named paper Prof. Dr. C. Stechert has reduced a large number of observations collected from various observatories, and has therefrom calculated the following definitive elements and the probable errors for the orbit of Brooks's comet (1887 II.):—

T = 1887 March 17·427594 ± 0·0061984 (M.T. Berlin)

$$\left.\begin{aligned} \omega &= 159°\ 26'\ 15''{\cdot}00 \pm 14''{\cdot}91 \\ ☊ &= 279°\ 56'\ 12''{\cdot}62 \pm \ 3''{\cdot}54 \\ i &= 104°\ 16'\ 10''{\cdot}47 \pm \ 3''{\cdot}18 \end{aligned}\right\} \text{Mean equinox } 1887{\cdot}0$$

log q = 0·2122261 ± 0·0000095
e = 0·9836922 ± 0·0002550.

Dr. Stechert's paper is also published in No. 3957 of the *Astronomische Nachrichten*.

AN INTERESTING METEOR TRAIL.—A peculiar meteoric phenomenon was observed by Senor J. A. Perez at Madrid on October 16, 1903. The meteor first appeared in Perseus at about 10 p.m., and the luminous trail did not entirely fade away until nearly 12 p.m. In the meantime its shape varied considerably. Commencing as an almost closed curve with a loop in it, the loop gradually developed until finally the primary curved trail almost entirely disappeared, leaving only a short faint portion entirely separated from the enlarged loop. Six drawings and a description of the phenomenon are published in No. 16 of *Das Weltall*.

THE ROYAL SOCIETY CONVERSAZIONE.

THE second of the two conversaziones held annually at the Royal Society took place on Wednesday, June 22. Many of the exhibits of recent scientific methods and results on view during the evening were shown at the conversazione held in May, and have already been described (May 19, p. 68), but there were, in addition to these, a number of new objects and experiments, of which a list is here given.

Spontaneous electrification of radium: Hon. R. J. Strutt. A specimen of radium salt in a glass tube is hung up by an

insulating support in an exhausted vessel. An electroscope is attached to the radium tube. Negatively electrified particles are shot off by the radium, and penetrate the glass tube, which is covered with a conducting coating of phosphoric acid, so as to act as an inductor. Thus a positive charge is left, and causes divergence. When the electroscope leaf touches the outer vessel, which is earthed, it collapses, and begins to charge up again. This will go on so long as the radium lasts.—Demonstration of oscillating electric discharges: Prof. A. Schuster, F.R.S., and Dr. G. Hemsalech. The separation of the components of a slowly oscillating electric discharge is effected by blowing a steady current of air through it. The discharge passes between two slightly inclined metal plates, and spectroscopic analysis shows the line spectrum of air in the initial discharge and the band spectrum of nitrogen in the oscillations. The metallic vapour from the electrodes does not seem to take part in the oscillations. The effect of introducing cores of iron or other metals into a coil giving self-induction may be illustrated by this arrangement.—The thermo-galvanometer: Mr. W. Duddell. The instrument is intended for the measurement of very small rapidly varying currents such as telephonic currents and the currents produced in the receiving vertical wire in wireless telegraphy. The sensibility of the instrument is such that either direct or alternating currents from a few micro-amperes upwards can be measured.—A new magnetic balance: Mr. W. Hibbert. The beam of a balance is made of a magnetised steel rod 27 centimetres long. The "centres" of the poles are 25 centimetres apart. The repellent pole of a second magnet being placed over one end of the beam causes this to descend, and the force of repulsion is balanced by a weight sliding on the other half of the beam.

Photographs and diagrams illustrating solar and meteorological changes, and a series of photographs to determine the relative temperatures of the stars: Sir J. Norman Lockyer, K.C.B., F.R.S. This exhibit included (1) enlarged pictures of the sun in "K" light taken with the spectroheliograph of the Solar Physics Observatory. (2) Diagrams illustrating the results of a discussion of sun-spot distribution; the relationship between the positions of solar prominences and the different forms of the corona; the different types, and their distribution, of the short-period barometric pressure variation over the earth's surface; and the close connection between the change of barometric pressure and rainfall. (3) Series of photographs taken with a quartz-calcite prismatic camera of 2-inch aperture and 18-inch focal length to determine the relative temperatures of stars. (4) Composite positives on glass of the sun's limb and disc, taken on the same plate with "K" light.—Photographs and drawings prepared from observations taken by the lightning research committee to illustrate the behaviour of lightning on certain buildings struck and damaged, notwithstanding their being provided with lightning conductors: Mr. Killingworth Hedges.—The physiotype: Mr. Francis Sheridan. This is a method of permanent printing without the use of inks, specially adapted to finger printing and the reproduction of designs from animal and vegetable life. The subject to be reproduced is pressed on paper, and by dusting the invisible impression with a coloured powder a dark and permanent print is produced.—Experiment showing the effect of internal stresses in glass upon light of different colours: Dr. L. N. G. Filon.—Photographic camera with free-swinging lens, and photographs taken with it: Dr. W. M. Flinders Petrie, F.R.S.—(1) Photomicrographs of interior of a rifle barrel; (2) photomicrographs of brass used for cartridge cases: Dr. W. R. Hodgkinson and Captain Hardcastle, R.A.

A new automatic vacuum pump: Mr. C. E. S. Phillips. The apparatus consists of a modified Toepler pump, so arranged that it works automatically through the operation of electrically controlled devices, for the purpose of producing extremely high rarefactions. The pump will reduce the gas pressure within a vessel of 200 c.c. capacity from that of the atmosphere to 0·002 mm. in fifteen minutes.—Vibrograph for recording vibrations photographically: the Cambridge Scientific Instrument Company, Ltd. The instrument is essentially similar to that used by Mr. A. Mallock, F.R.S., for recording vibrations caused by traffic on the Central London Railway.—An experiment illustrating harmonic undertones: Mr. H. Knapman.

The origin and growth of ripple mark: Mrs. Hertha Ayrton. The experiments shown illustrated the way in which the sand ripples are formed on the sea shore. If sand be spread quite evenly on the bottom of a trough, and water above the sand be oscillated so as to produce stationary waves, a small ridge is formed where the horizontal velocity of the water is greatest, next a ridge is started on each side of the first, which grows; then two more ridges are started, the former growing, and so on until the whole surface of the sand is ripple-marked. Each ripple now slowly moves towards the place of greatest horizontal velocity, while fresh ripples form near the places of least horizontal velocity. Pairs of ripples then coalesce here and there, and finally the greater part of the sand is assembled in a ripple-marked heap at the places of greatest horizontal velocity, this final result being attained, for example, in about twenty-five minutes in the case of the six-foot trough exhibited, when the stationary wave is twice the length of the trough. It was also shown that ripples are *not* produced by a *steady* current of water flowing over sand, but that by disturbing this steady current sand ripples may be formed, which, however, are erased on the current becoming steady again.

Crystalline glazes on pottery: Mr. William Burton and Mr. Joseph Burton. The specimens illustrated the decorative application to English earthenware and stoneware of certain recently discovered glazes which develop artificial crystalline silicates during the firing and cooling of the wares. In the "sunstone" and "fiery" crystalline glazes the crystals have the optical properties of micas, though their exact composition is at present undetermined. In the starry and opalescent glazes the radiating needles are akin to the mineral willemite, as is shown both by their optical properties and their composition.—Photographs of volcanic phenomena in the Lipari Islands: Dr. Tempest Anderson. The photographs, which were taken by the exhibitor in April of this year, show, besides the topography of the craters, several changes which have taken place in and about them since a former visit in 1888, and also some explosions from the crater of Stromboli which took place while Dr. Anderson was on that mountain.

Mimetic resemblance of the different forms of a single species of butterfly to two or three different models. Seasonal phases of South African butterflies of the genus Precis: Prof. E. B. Poulton, F.R.S. The fact that the non-mimetic male of the South and East African *Papilio dardanus* possesses three different forms of female, each mimetic of a different species of Danaine butterfly, was discovered by Mr. Roland Trimen, F.R.S. Within the last few months this discovery has for the first time been confirmed by breeding. The exhibited specimens, constituting the entire evidence thus obtained, were bred by Mr. George F. Leigh at Durban, Natal. The evidence of the wonderful seasonal changes in South African butterflies obtained by Mr. Guy A. K. Marshall has been further increased during the present year. His recently obtained evidence was exhibited, and consisted of a wet-season female of *Precis antilope* with its five dry-season offspring.—Colour photographs (Sanger-Shepherd process) of living moths and butterflies in their various stages of larva, pupa and imago: Mr. F. Enock.—(1) Living specimens of young flatfish; (2) methods of determining the age of plaice; (3) charts illustrating the natural history of the plaice in the North Sea; (4) charts illustrating the plankton and hydrography of the English Channel during 1903: the Marine Biological Association.—The cilioscribe, a machine to record the movements of cilia and the effect of physical conditions and chemical reagents upon them: Dr. W. E. Dixon and Mr. O. Inchley.—Specimens of West Indian fire-flies: the Zoological Society of London.

Photography of the movements of plants by means of the kammatograph: Mrs. D. H. Scott. The photographs are taken at intervals varying according to the rapidity of the movements of the plants during several days, and sometimes weeks. They are then shown on the screen in the kammatograph, and the movements of many days can be followed in a few seconds.—Models to illustrate the reduction (heterotype) divisions in animals and plants: Prof. J. B. Farmer, F.R.S., and Mr. J. E. S. Moore.

(1) Model of the external door of the Great Pyramid; (2) ellipsograph: Mr. R. Inwards.

SOME ANCIENT MAMMAL PORTRAITS.

Very little attention appears to have been hitherto devoted to the correct identification of the wild animals represented in the ancient Assyrian and Babylonian sculptures, and in the frescoes of Egypt under the Pharaohs. Antiquarians and Egyptologists seem in the main to have contented themselves with calling an animal a gazelle, an antelope, or a deer, without the slightest attempt to ascertain whether such titles are correctly bestowed, and in some cases utterly oblivious of the fact that deer (with the exception of the Barbary red deer and the fallow-deer in Tunisia, Algeria, and Morocco) are quite unknown in the African continent. A remarkable instance of this occurs in a comparatively recent publication of the Egypt Exploration Fund, forming the eighth memoir of the Archæological Survey of Egypt, entitled "The Mastaba of Ptahhetep . . . at Saggareh. Part i. The Chapel of Ptahhetep and the Hieroglyphs," by N. de G. Davies. Here a plate depicting a number of antelopes and goats is lettered "The Deer—East Wall." A moment's consultation with a naturalist friend would, of course, have saved the author from this absurd error.

Many of the animals represented in the sculptures and frescoes are obviously mythical; but others equally clearly represent species then living in the country, and these are for the most part so well and characteristically represented, that in many cases there is little or no difficulty in identifying the species to which they belong. Apart from the intrinsic interest of identifying the various species portrayed, a certain amount of information may at the same time be obtained with regard to the former distribution of the species in question, so that the investigation of the subject has considerable scientific interest.

Fig. 1.—Nubian ibex, from the Ptahhetep Chapel.

With these few preliminary observations, I proceed at once to the consideration of such figures as I have been able to identify with more or less certainty, merely adding that these for the most part represent ungulates, the portraits of Carnivora being far more difficult to assign to their respective species.

Commencing with the above mentioned figures from the east wall of the Chapel of Ptahhetep, for copies of which I am indebted to Mr. F. Ll. Griffith, the editor of the publication cited, there is no difficulty in identifying Fig. 1 with the Arabian, or Nubian, ibex (*Capra nubiana*). Although the knotted ridges on their front surfaces are not shown, the circular sweep of the horns is unmistakable, while further evidence for the specific identification is afforded by the long and pointed beard on the chin. It is, however, somewhat remarkable that in another representation of the same animal, from a hunting-scene on the east wall of this chapel, the beard is omitted; possibly one figure represents the animal in the summer dress, and the other in the winter coat. The shortness of the tail in both figures may be cited as a further instance of the artist's fidelity to nature.

Equally unmistakable and characteristic is the portrait of the aoul, or Soemmerring's gazelle (*Gazella soemmerringi*), which is reproduced in Fig. 2. The characteristic inward curvature of the tips of the horns is remarkably well shown, although the relative length of these appendages appears to be somewhat exaggerated. Contrasted with the figure of the ibex, the gazelle-like slenderness and length of limb, as well as the lightness of the whole build, are remarkably well brought out in this portrait. The short tail is also a characteristic gazelle feature. Soemmerring's gazelle, it may be observed, is still fairly abundant in Upper Nubia, and in past times may have been found much lower down the Nile delta.

The next three figures from the Ptahhetep Chapel represent long-tailed antelopes. Of these, the one shown in Fig. 3 is, I take it, probably the lesser kudu (*Strepsiceros imberbis*), if not this, the Abyssinian bushbuck (*Tragelaphus scriptus*); the length and strong twist of the horns render it, however, probable that the picture is intended for the former animal. The absence of a tuft of hair on the throat, as well as the relative size of the drawing and the narrowness of the ears, clearly show that the portrait is not intended for the greater, or true, kudu. Neither the lesser kudu nor the bushbuck are now known from Egypt, although they occur in Somaliland, Abyssinia, and probably Kordofan. The abundant hairing of the lower part of the tail is clearly indicated in the figure.

Fig. 2.—Soemmerring's gazelle, from the Ptahhetep Chapel.

From the spiral twist and length of the backwardly sweeping horns, the stout build, and the length of the tail, there can be little doubt that the animal portrayed in Fig. 4 is an addax (*Addax nasomaculatus*), a species of antelope met with at the present day throughout the desert tracts of northern Africa. The artist, it will be noticed, has made the profile of the face markedly concave, and thereby different from that of any of the other antelopes depicted.

Equally characteristic of the north African desert zone is the white, or sabre-horned, oryx (*Oryx leucoryx*), which differs from the other members of its tribe by the long horns sweeping backwards in a bold and graceful curve, instead of rising nearly straight up from the forehead. These features, as well as the long and thickly haired tail, are clearly represented in the portrait reproduced in Fig. 5, which may unhesitatingly be admitted to indicate the species in question. The white oryx is still a comparatively common antelope in the deserts of Upper Nubia and Kordofan. From the nearly straight and more strongly ringed horns, a figure of another antelope in the hunting-scene on the east wall of the Ptahhetep Chapel is intended, I think, for the beisa oryx (*Oryx beisa*), which ranges from the Red Sea littoral in the neighbourhood of Suakim through Abyssinia to Somaliland and north-east Africa generally.

Antelopes of other kinds, including some of the smaller gazelles, are recognisable on various Egyptian frescoes, but their exact specific determination is difficult or impossible. Cattle are frequently depicted, but all appear to be domesticated animals, none of which belong to the humped breed, now so common in Africa. Camels are occasionally represented, but there is nothing to show that these indicate the existence of this animal in a wild state in the country at that date; most probably, indeed, they are domesticated specimens. Very interesting, in a scene representing tribute-bearers from Cush (Goss's "Ancient Egypt," p. 37), is the portrait of a giraffe with a dog-faced baboon clinging to its throat. Curiously enough, the giraffe is

Fig. 3.—Lesser kudu (?) from the Ptahhetep Chapel.

represented with the legs spotted right down to the hoofs, after the fashion of the southern races of this species, and unlike the Nubian form, in which the spotting stops short at the knees and hocks. It must be acknowledged, however, that the artistic merit and attention to details are nothing like so good in the Cush tribute scene as in the Ptahhetep frescoes.

FIG. 4.—Male addax, from the Ptahhetep Chapel.

Among the Carnivora, the lion and the leopard are frequently depicted, but in the aforesaid frescoes of the tribute-bearers from Cush, the spots of the latter animal are represented as more like those of the ocelot. As might have been expected, the ichneumon, or Egyptian mungoose (*Herpestes ichneumon*), the snake-destroying propensities of which render it so venerated among the inhabitants of the Nile delta, is very frequently represented in the frescoes. It is well shown in Fig. 6, *A*., from the Ptahhetep hunting-scene. The fore part of the animal shown at *D* in the same figure seems to be intended for the little African fennec fox (*Canis famelicus*), the projecting appendix seen below the eye in the figure being apparently a conventional mode of representing the bristles or "whiskers," which are remarkably well developed in that species.

The long-tailed and long-hind-legged animal shown at *B* in Fig. 6 is apparently the lesser, or hairy-footed, jerboa (*Jaculus hirtipes*), the small size of the ears showing that it is not intended for the larger jerboa (*Jaculus aegyptiacus*). Another rodent shown in some of the frescoes, as in one of labourers bringing in sheaves of corn (Goss, *op. cit.* p. 195), is the Egyptian hare. The length of the ears, by which the animals are being carried, is, however, greatly exaggerated, the length of these appendages being nearly equal to that of the head and body.

A remarkable instance of fidelity to nature occurs in the two portraits of a hedgehog shown at *C* in Fig. 6, from the Ptahhetep hunting-scene, one of these representing the animal standing in the open, and the second showing it coming out of a hole with a locust in its mouth. The well developed ears clearly show that the species depicted is the long-eared hedgehog (*Erinaceus auritus*), which differs from its European cousin by the large size of the ears.

FIG. 5.—White oryx, from the Ptahhetep Chapel.

Turning to certain sculptures from Assyria, Babylonia and other parts of western Asia, I may in the first place direct attention to an illustration in Vaux's "Nineveh and Persepolis," entitled "Figure Carrying Gazelle," which is reproduced in the accompanying cut (Fig. 7). The original slab, which is preserved in the British Museum, was one of those obtained from the palace at Nimroud by Sir Henry Layard, in whose own work it bears the above-mentioned legend. Clearly such a title does manifest injustice to the genius and fidelity to nature of the ancient sculptor, who has faithfully portrayed the palmated and branching antlers and dappled hide of a fallow-deer, spots being, it is almost unnecessary to mention, quite unknown in any species of gazelle. The interest of this sculpture does not, however, by any means end here, for the details of the antlers and other features are sufficient to show that the species portrayed is evidently the Mesopotamian fallow-deer (*Cervus mesopotamicus*), which is a native of the Luristan province of Mesopotamian Persia, and was first definitely made known to European science by the late Sir Victor Brooke in 1875. That a species should have been thus clearly portrayed centuries and centuries ago by a sculptor of the

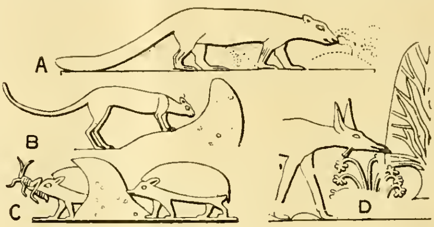

FIG 6.—Small mammals from the Ptahhetep Chapel. A, Ichneumon; B, Lesser jerboa; C, Hedgehog: D, Fennec.

Babylonian era, and should have remained unknown in western Europe until the close of the third quarter of the nineteenth century, is certainly a curious feature in the progress of human knowledge.

Of minor interest is another slab from Nimroud of which a cut appears in Vaux's above-mentioned volume, where it is lettered "Figure Carrying a Goat." The form of the horns, the general contour of the animal, and, above all, the absence of a beard on the chin, indicate, however, that the sculptor has represented one of the gazelles, which is probably the common Dorcas gazelle (*Gazella dorcas*), which at the present day has a wide distribution in North Africa, whence it extends into Palestine and Syria. It is, however, possible that the figure may be intended for the goitred gazelle (*Gazella subgutturosa*), which ranges from the Caucasus through Persia and Syria, and thence into Central Asia, where it is represented by a distinct local race.

FIG. 7.—Human figure carrying Mesopotamian fallow deer, from the Palace at Nimroud.

The last, but by no means the least interesting, sculpture to which I shall allude is one from Nimroud of which a woodcut appears on p. 225 of the work above cited, where it is described as a "Bull-hunt." The horns of the animals depicted are, however, as shown in the accompanying reproduction of the cut (Fig. 8), quite unlike those of the bulls represented in the Egyptian frescoes, and strongly recall those of the white-tailed gnu (*Connochaetes gnu*) of South Africa. Moreover, the tails of these animals are of the same type as those of the horses shown in this and other sculptures, and are quite different from those of the oxen of the sculptures and frescoes, which have a somewhat club-shaped form. It would appear, therefore, that the portrait is that of an animal with a fully haired tail

like a gnu or horse, and not one with a terminally tufted tail of the ox type. Again, the general form of the animal is much more like that of a gnu than of a bull.

Accordingly, there appears a very strong presumption that this sculpture represents the hunting of a species of gnu, and if this be really the case, it would be a fact of very considerable interest in connection with animal distribution. The two living species of gnu are now confined to Africa, but their near relatives, the hartebeests, range into Syria, while fossil species of that group, as well as of other antelopes of an African type, occur in the Upper Tertiary strata of northern India and China. Nothing is therefore more likely than that gnus should have formerly

Bull Hunt.

FIG. 3.—A gnu (?) hunt, from Nimroud.

had a more extensive range. If this be so, it would be one more argument in favour of the old view that the present antelope fauna of Ethiopian Africa immigrated into the country from the north, and against the modern theory of its autochthonous origin in Africa itself. For it is surely much more probable that animals should have died out in their ancient habitat and flourished in the country in which there are comparatively new arrivals rather than the converse.

A more extensive and detailed study of the old Assyrian and Babylonian sculptures and of the Egyptian frescoes would doubtless lead to the identification of species of animals other than those mentioned above; but such identifications as I have been able to make are sufficient to demonstrate that the subject has a definite bearing on the past distributional history of mammals, and that it ought not to be neglected by students of that branch of zoology.

R. LYDEKKER.

THE ACTION OF RADIUM EMANATIONS ON DIAMOND.[1]

WHEN diamonds are exposed to the impact of radiant matter in a high vacuum they phosphoresce of different hues, and assume a dark colour, becoming almost black when the bombardment is long continued (*Phil. Trans.*, 1879, part ii., p. 658, par. 625).

Some diamonds blacken in the course of a few minutes, while others require an hour or more to discolour.[2] This blackening is only superficial, and although no ordinary means of cleaning will remove the discoloration, it goes at once when the stone is polished with diamond powder. The fact that the black stain is not affected by ordinary oxidising reagents would seem to show that it is not due to a layer of amorphous carbon; but it might be graphite, which is much more resistant to oxidation. Becquerel has shown that graphite is converted into graphitic oxide by long digestion in a warm mixture of potassium chlorate and strong nitric acid, while diamond—even in a very finely powdered state—is absolutely unaffected by the mixture (*Ann. de Chim. et de Phys.*, [4], vol. xix. p. 392).

Some forms of graphite dissolve in strong nitric acid; others require a mixture of highly concentrated nitric and potassium chlorate to dissolve them, and even with this intense oxidising agent some graphites resist longer than others. M. Moissan has shown that the power of resistance to nitric acid and potassium chlorate is in proportion to the temperature at which the graphite has been formed, and with reasonable certainty we can estimate this temperature by the resistance of the graphite to this reagent.

Judging from the long time required to remove the superficial darkening from diamond, the graphite is as resistant as that formed at the temperature of the electric arc.

On one occasion when I had blackened the surfaces of diamonds by molecular bombardment *in vacuo* M. Moissan was present, and took some away with him for further examination. He subsequently reported the results in the *Comptes rendus*, vol. cxxiv., No. 13. He heated the diamond to 60° in an oxidising mixture of potassium chlorate and fuming nitric acid prepared from monohydrated sulphuric acid and potassium nitrate fused and quite free from moisture. The action on the black layer is very slow. There is produced graphitic oxide, which at an increased temperature yields pyrographitic acid, which is easily destroyed by nitric acid. Hence the variety of carbon which coated the diamond was graphite. The transformation of diamond into graphite requires the high temperature of the electric arc. The higher the temperature to which graphite is raised the greater is its resistance to oxidation. M. Moissan concludes that the temperature reached by the surface of the diamond in my radiant matter tubes is probably about 3600°.

The β-rays from radium having like properties to the kathode stream in a radiant matter tube, it was of interest to ascertain if they would exert a like difference on diamond. Two Bingara diamonds, A and B, weighing respectively 0·960 and 1·020 grains, were selected as near as the eye could judge of the same size and colour—very pale yellow, technically known as "off colour." Diamond A was put in a drawer far removed from radium or any radio-active body. Diamond B was kept close to a quartz tube containing about 15 milligrams of pure radium bromide sealed *in vacuo*. It phosphoresced brightly and continued to glow the whole time of the experiment.

After a fortnight the two diamonds were put side by side and compared. I could see no appreciable difference in colour between them. Diamond B was now replaced close to the quartz tube of radium, and they were kept in contact for six weeks. At the end of that time examination again showed scarcely any difference between the two. The one which had been near the radium might be a little the darker of the two, but the difference was too slight to enable me to speak positively.

Diamond B was now put inside a tube with radium bromide, the salt touching it on all sides, as it was thought possible that a screen of quartz might interfere with the passage of emanations which would act on the diamond. The comparison diamond was kept removed from the emanations as before. The experiment was continued for seventy-eight days, when the two diamonds were again examined. There was now a decided difference in colour between them; diamond A was of its original pale yellow "off colour," and diamond B was of a darker appearance and of a bluish tint, with no yellow colour apparent.

It thus appears that the property which radium emanations possess of darkening transparent bodies which they impinge upon—a property very marked in the case of glass, and less with quartz—also holds good in the case of diamond.

Diamond B was now heated to 50° C. in a mixture of strongest nitric acid and potassium chlorate for ten days, the mixture being renewed each day. At the end of this time the diamond had lost its dull surface colour, and was as bright and transparent as the other stone, but its tint had changed from yellow to a pale blue-green.

The radium emanations have therefore a double action on the diamond. The β-rays (electrons) effect a superficial darkening, converting the surface into graphite in a manner similar to, but less strongly than, the more intense electrons in the kathode stream. But the alteration of the body colour of the stone by emanations which are obstructed by the thinnest film of solid matter, even by a piece of thin paper, is not so easy to understand. A superficial action might be expected, but not one penetrating through the whole thickness of the diamond. I believe the alteration

[1] Read before the Royal Society on June 16 by Sir William Crookes, F.R.S.

[2] At a lecture before the Royal Institution on June 11, 1897, I exposed a flat macle crystal of diamond to radiant matter bombardment before the audience for about five minutes, a strip of metal covering part of the stone. On removing the diamond from the vacuum tube and projecting its image on the screen with the electric lantern, the image of the darkening was very apparent.

of colour is a secondary effect; in presence of radium the diamond is extremely phosphorescent, and it continues to shine during the whole time of the experiment. This constant state of vibration in which the diamond was kept for many weeks may have caused an internal change revealing itself in a change of colour. Indeed, it is not difficult to suppose that a chemical as well as a physical action may result. If the yellow colour is due to iron in the ferric state a reduction to the ferrous state would quite account for the change of colour to a pale blue-green.

This alteration of colour may be of commercial importance. If "off colour" stones can be lightened their value will increase, while if the prolonged action of radium is to communicate to them a decided colour they would be worth much more as "fancy" stones.

[*Added June* 16.—After the ten days' heating in the above acid mixture the two diamonds were put together in a glass tube and carried about for twenty-five days, sometimes loose and sometimes in the tube. They then were laid near together on a sensitive film in total darkness for twenty-four hours. On developing, diamond B had impressed a strong image on the film, but only a very faint mark could be seen where the other diamond had been. Probably this slight action was due to a little radio-activity induced in A during its twenty-five days' proximity to B.

The experiment was then repeated for confirmation, allowing the diamonds to remain on the sensitive surface for only five hours. On development, a good image of diamond B was seen, but not so black as in the former case.

The fact that diamond B was strongly radio-active after it had been away from radium for thirty-five days, for ten of which it was being heated in a mixture powerful enough to dissolve off its outer skin of graphite, seems to me proof that radio-activity is by no means a simple phenomenon. It not merely consists in the adhesion of electrons or emanations, given off by radium, to the surface of an adjacent body, but the property is one involving deep-seated layers below the surface, and like the alteration of tint is probably closely connected with the intense phosphorescence the stone had been experiencing during its seventy-eight days' burial in radium bromide.]

THE MARKINGS AND ROTATION PERIOD OF MERCURY.

MUCH new light was thrown upon the rotation period of Saturn during the year 1903, and it seems highly probable that the next planet to afford us information as to the same feature will be the planet Mercury. Spots of very definite and distinct character are certainly visible on the surface of this fugitive little orb, which offers a more promising field for new discoveries than Venus, though it is considerably smaller, at a much greater distance from us, and more unfavourably placed for observation. The markings sometimes perceptible on Mercury appear to be of sufficient prominence to be followed, and if really capable observers are forthcoming, at the opportune period, to study them, it will be possible to ascertain once and for all whether this circumsolar planet turns on its axis once in about 24 hours or 88 days, and an important advance in our knowledge will have been made.

Spots have been discerned on Mercury since the time of Schroeter about a century ago. Among those who have obtained observations of them are the following:—

Schroeter	1800	Denning	1882
Harding	1801	Schiaparelli ...	1882–3
Bessel	1801	Brenner	1896
Prince	1867	Lowell	1896
Birmingham ...	1870	Barnard	1900
Vogel	1871	McHarg .. .	1904

In 1800 Schroeter announced that the rotation period was about 24h. 4m. from blunted appearances of the southern horn, but doubted if the value could be determined to within a few minutes. In 1801 Harding perceived a dusky spot in the southern hemisphere, and derived the period as 24h. 5m. 30s. Further observations, however, obtained by himself and Bessel caused him to reduce this period to 24h. 0m. 50s. Bessel found 24h. 0m. 53s. from several of Schroeter's observations extending over fourteen months. In 1882 Denning, at Bristol, thought a period of about 25 hours would satisfy the observations, but Schiaparelli, in the pure Italian sky, arrived at very different results, and concluded that the planet rotated in 88 days, or in the same period as he revolved round the sun. Quite recently McHarg found the time 24h. 8m. from his own observations of a dark spot in April, 1904. He also deduced a period of 24h. 5m. 48s. from a blunting of the southern horn seen by Schroeter in 1800 March, and by Denning in 1882 November.

ON THE DIMENSIONS OF DEEP-SEA WAVES, AND THEIR RELATION TO METEOROLOGICAL AND GEOGRAPHICAL CONDITIONS.[1]

THE following table has been compiled from the original sources after re-calculating the true velocities corresponding to the "Beaufort numbers" in accordance with the alteration of reduction factor adopted by meteorologists since the date of the observations:—

Table showing the Relation between the True Velocity of the Wind in Statute and in Geographical Miles per Hour and the Height of the Wave in Feet, as deduced from Observations by numerous French Observers extending over many years and taking in all the Oceans.

No. of wind on Beaufort's scale of 0–12	Velocity of wind, stat. miles per hour	Velocity of wind, geographical miles per hour	Height of wave in feet	Authority	Velocity of wind in stat. miles per hour divided by height of wave in feet	Velocity of wind in geographical miles per hour divided by height of wave in feet

10·8	61·8	53·7	27·89	Antoine	2·22	1·93
				Average	2·03	1·78

This table gives the average of many hundreds of days' observations conducted at various times during a period of about forty years by independent observers, all French seamen of the navy or merchant service, carried out in almost all parts of the oceans ordinarily visited by ships, and from many different vessels (none, however, of the great size of our modern liners, and therefore better for such observations), and shows the average height of the wave, in open sea with sufficient depth of water, to be in simple arithmetical proportion to the velocity of the wind, *the height of the wave in feet being in round numbers one-half of the velocity of the wind in statute miles per hour.*

This result does not express a dynamical law; it is simply

[1] Extracted from a paper by Dr. Vaughan Cornish in the *Geographical Journal* for May, 1904.

the result of averages, but if confirmed by further observation it will have considerable interest for geographers, meteorologists, and for those who have to do with the sea.

We may take 20-feet average waves and 30-feet occasional waves as the limit in very severe gales in the "seas," and 30-feet average and 45-feet "ordinary maximum" waves as the limit of wave-height for the oceans. Although strong winds will push short waves to a considerable steepness, yet they are not able to attain quite so great a height as somewhat longer waves, because, moving more slowly, their tops give way under the great difference of wind-pressure upon their two sides. Thus the development of the larger waves primarily depends upon the opportunity to attain greater *length*. It is in this respect that our consideration of the size of the cyclone becomes so important for deep-sea waves, especially for explaining the co-existence of the steep storm waves with the swell.

The slighter development of the longer waves is undoubtedly influenced by the dual circumstance that the length of fetch of wind of the required velocity diminishes (the stronger winds only blowing for a short *time* at a fixed station, or for a short *space* in the travelling cyclone), whilst the requisite fetch is greater, for it must be a *large multiple of the wave-length*. Thus the limit of length of the steep waves is rapidly approached from the concurrence of the two causes operating, so to speak, from opposite directions.

Taking T. Stevenson's table ("Enc. Brit.," ninth edition, art. Harbours) of the relation of height of waves to length of fetch, and multiplying the heights by twenty (as a first approximation) to obtain the length, we see that a considerable wave does not become the dominant form except with a fetch *approaching* 2000 *times its wave-length*.

Extending these results to 30-feet (average) waves 600 feet long, *i.e.* fully grown ocean storm waves, we see that 30-feet $\times$ 20 $\times$ 2000 = 227 statute miles, or 197 geographical miles.

A 9-hours' blow, with wind 64 miles per hour, was recorded in the gale of December 22, 1894. With the average velocity of advance of deep depressions from W.S.W. on our coast, viz. 24·8 (say 25) knots, this would give a length of fetch of 225 geographical miles. The height of wave corresponding to this length of fetch in severe gales, as calculated by stretching Stevenson's formula, is 22·5 feet. If the cyclone had the exceptional speed of 60 knots, the length of fetch of the 64-mile-an-hour wind would be 450 miles, which with Stevenson's formula gives a height of 31·8 feet. A thirty-foot wave from the same formula requires a length of fetch of 400 miles. Both this length of fetch and this height of wave are probably more normal in the southern ocean than in the North Atlantic; the 22·5-foot wave and the 225-mile length of fetch would be more the scale of things there.

If we take the case of a very long swell of 2000-feet wave-length (unusual, but within the records), which is one-third of a geographical mile, then 2000 times this wave-length is 666 miles. The speed of such a swell is 69 knots, and wind of greater velocity than this would only be blowing in a comparatively short strip of even a great cyclone. They would, therefore, not be developed into the dominant wave form, however strong the wind might be there. The reason for this is most easily understood if we imagine a short series of such waves to exist with the steepness of ordinary storm waves. If 76-miles-per-hour wind last one hour at a fixed station (which occasionally happens on our coasts), and the rate of advance of the storm be 25 miles per hour, then the stretch of water at any time exposed to the above force of wind is 25 miles, which would comprise only 75 such waves.

Suppose these, or any of them, to have attained considerable steepness, it is evident that the arrangement would be unstable, for there would be so great a difference of steepness between neighbouring waves that the group would speedily extend itself, multiplying the number of its waves and flattening them out, until the gradation from one wave to the next is almost indefinitely small.

Although the length of fetch in cyclones is inadequate to the development of the longer observed swells to great steepness, the length of run of the cyclones on the oceans is frequently such as afford much more than the time required for the full development of ordinary storm waves. Thus a cyclone travelling a little less than 25 knots, the average speed of deep depressions approaching our shores from the Atlantic, travels with the group velocity of a swell of 16-seconds' period (or 1311-feet wave-length), the speed of such waves being 48·56 knots, and their group velocity being, therefore, 24·28 knots. Such a storm, if brewed in mid-Atlantic, and advancing on our shores from W.S.W., would continually reinforce this swell during three days, a space of time equal to 16,200 times the period of the wave.

It is an interesting coincidence that the average velocity of deep depressions approaching our coasts from points between W.S.W. and W.N.W. (25 knots) is about half that wind velocity called "a severe gale" by Brodie (viz. Beaufort's 10, 53 statute miles per hour, 46 knots). Of the sixty recorded cases of more rapidly advancing storms, twenty-five had a speed of 31 to 34 knots, which is again about half the maximum observed wind velocity (except in gusts).

Thus we have a dual correspondence of velocities, the individual wave of the longest swells moving with nearly the velocity of the strongest winds, and the group of swells advancing with nearly the velocity of the great storms.

When, as often happens (in the North Atlantic), a long swell precedes and predicts the arrival of a storm, the rate of advance of the latter is less than half the speed of this swell in deep water.

A slowly moving storm with violent winds will raise a short steep sea with comparatively little swell in it.

The rate at which a wave flattens out when the wind ceases is inversely as the square of its length. Consequently, in oceans large compared with the areas of cyclonic storms, the surface is found to be heaving with a long swell during the intervals between storms (whence the grand surf which rolls in upon oceanic islands). New storms will not, as a rule, catch up a group of such swells, but cyclones brewed upon the ocean find such a swell already running, and, travelling with it, soon increase its steepness. This is particularly true of the circumterrestrial waters of the southern hemisphere, where a long swell from the west is always running.

It is probable (and experience at sea supports the opinion) that in moderately high latitudes of the southern hemisphere, say 40° to 60° S., the cyclones are on a larger scale than in the corresponding latitudes of the northern hemisphere, where atmospheric movements are more broken up by the alternation of land and water. The bigger waves of the southern ocean I attribute only indirectly to the greater expanse of water. The expanse of water in the northern Pacific and northern Atlantic would amply suffice for the development of larger waves than actually occur there were the storms which traverse them framed on a larger scale.

GEOLOGY IN NORWAY.

THE last "Year-book of the Norwegian Geological Survey" (1903) contains five papers bearing on different subjects concerning the geology and topography of Norway.

In the first paper, the aged mining engineer Mr. Friis deals with Jurassic coal beds on the Andö, an island in northern Norway. The sandstones and slates of the Brown Jura contain good cannel coal of 1 metre thickness, but cover rather a small area.

In the second paper, Dr. H. Reusch, the chief of the Survey, describes a journey through the interior of the most northern province of Norway, a desolate and almost uninhabited country, to visit the gold fields near the Russian border. Gold occurs in a Glacial deposit, "aas" or esker, but only in small quantities. Dr. Reusch describes the country upon the whole as a peneplain 300 to 500 metres above the sea. Glacial deposits widely cover the land, and solid rock, mostly archæan and sandstones of supposed Devonian age, is only seldom seen.

In two papers, Mr. Kaldhol and Mr. Rekstad deal with the succession on "Hardangervidda," the wide plateau on an average 1300 metres above the sea, with peaks ranging

almost to 2000 metres, to the east of the Hardangerfjord. On the underlying granite rests a phyllite series, containing at the base black schists with *Dictyonema flabelliforme*, giving the series a place within the Upper Cambrian and Lower Silurian. But above this phyllite, and perhaps concordantly, rest metamorphic schists, beginning with quartzite beneath and ending in a coarse, typical gneiss. Some geologists are inclined to think this inversion due to an immense overthrust. The boundary between the granite and the phyllite is very level, and Mr. Rekstad suggests the surface of the granite to be an Archæan or Cambrian peneplain. The paper is accompanied by a coloured map of the region.

In the last paper Mr. Rekstad shows that the upper limit of the mountain forests has of late subsided 300 to 400 metres in southern Norway, pointing to a decrease in temperature of 2·1° to 2·4° C. In the time of mild climate glaciers must have been almost absent. He places this time to the age of the *tapes*-banks, when the land had performed about four-fifths of its total upheaval since the close of the Glacial period.

The papers are all illustrated by photographs and diagrams. They are written in Norwegian, but each is accompanied by a summary in English. A. D.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Oxford.—At the Encaenia on June 22, the honorary degree of D.Sc. was conferred upon the following:—The Hon. C. A. Parsons, Mr. Marconi, Sir William S. Church, Sir Andrew Noble, Sir William Crookes, Sir David Gill, Sir John Murray, Prof. Alfred Marshall, Prof. J. J. Thomson, Prof. Horace Lamb, Prof. A. R. Forsyth, Prof. J. Dewar, and Prof. J. Larmor.

Cambridge.—In the natural sciences tripos forty-five men and one woman have gained first classes in part i.; thirteen men and three women have gained first classes in part ii.

The Raymond Horton-Smith prize, for the best M.D. thesis of the year, has been awarded to Dr. F. A. Bainbridge, Trinity. Dr. B. N. Tebbs, Queens', receives honourable mention.

The Harkness studentship in geology has been awarded to Mr. O. T. Jones, Trinity.

Dr. H. B. Roderick, Emmanuel, has been appointed demonstrator of surgery.

The Frank Smart studentship of 100*l*. a year for research in botany will be filled up in July. Applications must be sent to the Vice-Chancellor by July 13.

The degree of doctor of science was conferred on Prof. C. S. Sherrington, F.R.S., at the congregation on June 18.

The Wiltshire prize for geology and mineralogy is divided between H. A. Wootton, Clare, and J. A. Crowther, St. John's.

The Hockin prize for physics at St. John's is also divided, between S. H. Phillips and J. A. Crowther.

The Hutchinson studentship for research in physics is awarded to E. Gold, bracketed third wrangler 1903.

Mr. W. G. Fearnsides (natural sciences tripos, 1900) has been elected a fellow, and Dr. E. H. Griffiths, F.R.S., principal of Cardiff University College, has been elected an honorary fellow, of Sidney Sussex College.

Dr. O. Aschan has been appointed professor of chemistry at Helsingfors.

The following honorary degrees were conferred at a convocation of the University of Durham on June 22:—D.C.L., Sir Daniel Morris; D.Sc., Prof. R. A. Sampson, F.R.S.; D.C.L., Dr. Harold F. Wilson; D.Sc., Mr. David Woolacott.

The first number of the second volume of the *Investigations* of the Departments of Psychology and Education of the University of Colorado has been received. It contains papers by Mr. F. H. Clark on the scope and efficiency of the normal schools of the United States; by Prof. Libby on co-education and the raw material of the school; and by Mr. J. H. Bair on factors in the learning process.

The programme containing regulations for the registration, conduct, and inspection of classes and examination of candidates in technological subjects, and for the award of teachers' certificates in manual training and domestic economy, for the session 1904–5, in connection with the City and Guilds of London Institute, has now been published. The programme may be obtained from Mr. John Murray, price ninepence net.

We have received from Messrs. Swan Sonnenschein and Co., Ltd., a copy of a useful publication compiled from official records by the editor of the "Schoolmaster's Yearbook and Directory." The title and subtitle serve to indicate satisfactorily the scope of the new volume, which is called a "Register of Teachers for Secondary Schools," being the list of teachers registered in column B of the Teachers' Register, formed and kept by the Teachers' Registration Council, in accordance with the Order in Council, March 6, 1902, and amending orders. Particulars of address, date of registration, qualifications, experience, recorded in the register for each teacher, are also given. The volume costs two shillings net.

A paper read last July at the meeting of the National Educational Association at Boston, Mass., U.S.A., by Prof. W. N. Rice, on the proper scope of geological teaching in the high school and academy, has been reprinted in separate form from the *Proceedings* of the National Educational Association. From a copy of the reprint which has reached us, we learn that Prof. Rice believes "that there should be a required course in physical geography in the first year of the high-school curriculum." The geographical course would by this plan precede the bifurcation of the curriculum necessitated by the fact that in most cases the classical students must begin Greek in the second year. Prof. Rice also considers that a course in geology, which should be chiefly dynamical and structural geology, is a most desirable elective in the fourth year of the curriculum.

The University College of North Wales has organised a department of forestry or sylviculture in connection with its agricultural department. The desirability of providing facilities for the teaching of forestry in North Wales was brought prominently forward by Lord Onslow some months ago in his address at the opening of the College Farm at the commencement of the present session, and it is gratifying to find that the proposed scheme has so soon been realised. Mr. Fraser Storey has been appointed lecturer in forestry. Not only will the Bangor School of Forestry be the first institution of its kind organised in connection with a university college in this country, but a further innovation has been made in extending the work of the department beyond the limits of ordinary class-teaching. A considerable portion of Mr. Storey's duties will consist in acting as an expert adviser in connection with the principal estates in the district, on which the development of forestry is desirable.

The Earl of Onslow on Friday last, June 24, opened the gardens of the horticultural department of University College, Reading, in his official capacity as President of the Board of Agriculture. It may be pointed out that for some years Mr. Frederick Keeble has given instruction in the principles of horticulture, but only comparatively recently is it that, owing to the kindness of Mr. Alfred Palmer in putting seven acres of land, conveniently placed, at the disposal of the college, justice has been done to the practical side of the work. At the ceremony to which we have referred, the principal, Mr. W. M. Childs, answered the question as to why horticulture is necessary, and gave three reasons:—(1) the enormous increase in scientific knowledge as to the growing of plants; (2) foreign competition; and (3) the training of teachers in connection with rural education. Lord Onslow, in a brief speech, emphasised the remarks of the principal; he dwelt particularly on the third point, and alluded to the need for properly presenting produce to the purchaser. Mr. Martin J. Sutton afterwards said that never before had he attended a meeting at which the teaching of horticulture had received the official recognition of the Government. Seeing the hard struggle which has been made to introduce such teaching of horticulture as gives proper attention to the scientific side, the results which we chronicle are most satisfactory.

THE academic address to the University College of North Wales was delivered on Friday last by Sir Arthur Rücker, F.R.S., principal of the University of London, who chose as his subject "University Organisation in Great Britain." Sir Arthur Rücker traced the various phases through which the university systems of our country had passed, starting with the residential university, represented at the present time by Oxford and Cambridge (and in former days by Stamford). Next in order of development came the purely examining University of London, which led to the formation of provincial university colleges. The federal university came next in the Victoria University and University of Wales. The University of Birmingham represented a new phase, namely, the municipal university, of which at the present time there were two representatives in Lancashire and two in Yorkshire. The impossibility of raising by private subscriptions sufficient funds for the endowment of universities and university colleges resulted in the necessity of Government subsidies, and a great deal more ought to be expected in this direction in the near future. In the further development of university organisation a number of interesting questions would have to be answered. These related to such points as how far Government assistance was to be given to colleges and how far to universities, whether institutions partaking of the character both of colleges and universities should be subsidised under both headings, whether it was desirable to confer on new universities generally the powers of examining external students as provided for in the charter of the Birmingham University, and the extent to which universities subsidised at the same time by municipalities and the Government should be under the inspection of both bodies.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 2.—"Colours in Metal Glasses and in Metallic Films." By J. C. Maxwell **Garnett.**

The first part of the paper is devoted to coloured glasses. The phenomena which it seeks to explain were observed by Siedentopf and Zsigmondy.

It is proved in this paper that every medium made up of metal spheres embedded in a non-absorbing substance in such manner that the average distance between two adjacent spheres is much less than a wave-length of light has a perfectly definite colour, depending only on the optical constants of the metal of which the spheres are made, on the refractive index of the substance in which they are embedded, and on the quantity of metal present, but not on the size or distance apart of the spheres.

It is shown that the particles which Siedentopf and Zsigmondy observed in gold glasses are spherical when their diameters are less than 10^{-5} cm. The presence of the metal spheres accounts for the red colour of gold and copper ruby glass, and for the yellow colour of silver glass, and would give a blue-violet colour to "potassium-sodium" glass (potassium-sodium being an amalgam of which the optical constants have been determined by Drude).

Experiments are described proving that these characteristic colours can be produced in a colourless metal glass containing the metal in solution or in combination (the state in the manufacture of gold or copper ruby glass before the second heating) by the β radiation from radium.

The calculated properties of media containing many metal spheres to a wave-length of light account for the changes of colour, for the initial increase in absorption, and for the final change to almost complete transparency which Mr. G. T. Beilby observed during the annealing of gold and silver films. Explanations are given of the changes of colour on heating observed by Prof. R. W. Wood in potassium and sodium films deposited on the insides of exhausted glass bulbs. The increase in strength of colour which was generally observed in the light transmitted by these films when the plane of polarisation of obliquely incident light was changed from that of incidence to a perpendicular position is also explained.

Evidence is adduced to show that the allotropic silvers obtained by Carey Lea are further examples of this type of medium.

"A Method of Measuring directly High Osmotic Pressures." By the Earl of **Berkeley** and E. G. J. **Hartley.** Communicated by W. C. D. Whetham, F.R.S.

This is a preliminary paper describing the authors' method of determining high osmotic pressures. It is as follows:—

A porous porcelain cylinder, glazed only at the ends, has a copper ferrocyanide membrane deposited on its outer surface. The solution surrounds the cylinder, and the inside, which is connected to a graduated glass capillary, is filled with water. By means of a plunger, which works in a steel cylinder and is actuated by a lever and weights, pressure is put upon the solution. So long as this pressure is less than the osmotic pressure of the solution, water from the inside of the cylinder passes through the membrane into the solution, and consequently the water-level in the capillary falls. When the pressure on the solution is gradually increased, the rate at which the level falls gradually decreases, and this continues until the osmotic pressure of the solution is reached; then the level in the capillary is stationary. A further increase of pressure on the solution will then cause the level to rise. The rate of movement of the level in the capillary is a function of the difference between the osmotic pressure and the pressure on the solution, so that by observing the changes in this rate consequent on the corresponding changes in the pressure, the point at which the latter is equal to the osmotic pressure can be deduced. The results of some experiments with cane sugar, extending up to a solution having an osmotic pressure of 45 atmospheres, are given.

The semipermeable membranes are made partly by following Pfeffer and partly by a modification of Morse's electrolytic method. By this means a membrane that withstood 120 atmospheres pressure was obtained.

"On the Electric Effect of Rotating a Dielectric in a Magnetic Field." By Dr. Harold A. **Wilson.** Communicated by Prof. J. J. Thomson, F.R.S.

It was shown by Faraday in 1831 that an electromotive force is induced in a conductor when it moves in a magnetic field so as to cut the lines of force. The object of the experiments described in this paper was to see if a similar electromotive force is induced in a dielectric when it moves in a magnetic field.

According to Maxwell's electromagnetic theory as developed by H. A. Lorentz and Larmor, such an electromotive force should be induced in a dielectric, and should be equal to that in a conductor multiplied by the factor $1-K^{-1}$, where K is the specific inductive capacity of the dielectric.

The method employed was to rotate a hollow cylinder of ebonite in a magnetic field parallel to the axis of the cylinder. The inside and outside surfaces of the cylinder were provided with metal coatings, with which electrical contact was made by sliding brushes. The inside coating was connected to earth, and the outside coating to one pair of the quadrants of a sensitive quadrant electrometer, the other pair of quadrants being connected to earth. The magnetic field was then reversed, so reversing the induced electromotive force in the ebonite. The resulting electric displacement was measured by means of the electrometer, the quantity of electricity required to produce a given deflection of the electrometer needle being determined by means of a small parallel plate guard ring condenser.

The cylinder used was 10 cm. long and $2r_2=4\cdot15$ cm., $2r_1=2\cdot01$ cm. It was mounted in a solenoid having 95 turns per cm., by which a magnetic field of strength 1500 could be produced. The cylinder was driven by a $\frac{1}{2}$ horse-power motor, and could be run at 200 revolutions per second.

The mean result obtained for the quantity of electricity set free on the outside coating of the cylinder, on reversing the magnetic field, only differs from the amount calculated theoretically by 1 per cent. The specific inductive capacity of the ebonite, as determined by measuring the capacity of the cylinder, was 3·54, while the value calculated from the results obtained was 3·64.

The results obtained are thus in complete agreement with the theories of Lorentz and Larmor, and may be regarded as a confirmation of these theories.

June 9.—"On the Combining Properties of Serum-Complements and on Complementoids." By Prof. Robert **Muir** and Dr. Carl H. **Browning**. Communicated by Sir J. S. Burdon-Sanderson, Bart., F.R.S.

The following are the chief results obtained from the experiments described in this paper. It is, of course, to be understood that they are held to apply only to the cases investigated, viz. the immune-body for ox's corpuscles obtained from the rabbit, used along with rabbit's and guinea-pig's complements and complementoids. Further observations will be necessary to determine whether they obtain generally.

(1) The existence of complementoids in heated sera can be shown in ordinary test-tube experiments, by their preventing (*a*) the union of complement with anti-complement, (*b*) the union of complement with R+IB molecules after lysis.

(2) The amount of complementoid derived from complement as tested by the combining relationships varies; in the case of the rabbit it is approximately equal to the original amount of complement; in the case of the guinea-pig it is considerably less than that amount.

(3) The combining affinity of complementoid, both for anti-complement and for R+IB molecules after lysis, is not much inferior to that of complement.

(4) On the other hand, complementoid has a feeble affinity for R+IB molecules before lysis, *i.e.* for intact red corpuscles treated with immune-body; of the complementoid added only a small quantity enters into combination; hence complementoid does not prevent lysis by complement.

(5) When red corpuscles united with multiple doses of immune-body are lysed by a single dose of complement, the surplus R+IB molecules can be saturated with excess of complementoid, so that almost no complement can subsequently be taken up. This result is obtained also with rabbit's complementoid and guinea-pig's complement, and with guinea-pig's complementoid and rabbit's complement.

"On the Ossiferous Cave-Deposits of Cyprus." By Dorothy M. A. **Bate**. Communicated by Dr. Henry Woodward, F.R.S.

"Further Note on the Remains of *Elephas cypriotes*, Bate, from a Cave-Deposit in Cyprus." By Dorothy M. A. **Bate**. Communicated by Dr. Henry Woodward, F.R.S.

Entomological Society, June 1.—Prof. E. B. Poulton, F.R.S., president, in the chair.—Mr. E. B. **Green** exhibited various insects from Ceylon, including a "carpenter bee" (*Xylocopa fenestrata*, Fab.) and a large asilid fly (*Hyperechia xylocopiformis*, Wlk.) which very closely mimics it; specimens of a Mycetophilid fly and cocoons from which they emerged, showing their beautiful structure; and examples of a tineid moth with remarkable larval cases.—Mr. H. St. J. **Donisthorpe** exhibited specimens of the rare *Tachys parvulus* from the New Forest.—Mr. J. E. **Collin** exhibited specimens of *Mochlonyx velutinus*, a rare British Culicid which he, in company with Messrs. Verrall and Wainwright, had found in numbers near Beaulieu, in Hampshire, on May 22.—Mr. A. J. **Chitty** exhibited an Ophionine ichneumon with the pollen of an orchid firmly attached to the head, making the insect look as though it was attacked by fungus.—Mr. C. P. **Pickett** exhibited long series of *Angerona prunaria* and *Lycaena corydon* showing the remarkable range of variation in both species.—The **President** exhibited specimens of *Paltothyreus tarsatus*, Fabr., an ant belonging to the family Poneridæ, recently received from Dr. S. Schönland, who mentioned that about eight miles west of Palapye Road Station, Cape Colony, he had noticed an awful stench, which, however, passed off after a time. It turned out afterwards that it emanated from these ants living in trees.—The **President** also exhibited a cluster of the green eggs of *Vanessa urticae* fixed to the under-side of a small leaf towards the summit of a nettle-stem. The cryptic resemblance of the eggs to their environment was very remarkable. He then read a note on the courtship and pairing of the species.—Dr. T. A. **Chapman** exhibited two very interesting Erebias caught by the president on the Guadarrama (near Madrid, Spain) on July 25, 1902, at an elevation of about 6000 feet. Though taken together and very much alike, they proved to be of two species, viz. *E. evias* and *E. stygne*, both males. He remarked that the same two species which he found last year in Spain associated together and closely resembled each other, which is not their habit in Switzerland. He also exhibited the ova, larval work, pupæ, and imagines of Anthomyiina, sp., a dipteron that lays its eggs on a fungus, *Epichloe typhina*, Buk., common in June on grass stems. He had often wondered at the curious way of life of this larva, living under a case and burrowing out on the surface of the fungus, making labyrinthine tracks when it ate the incipient spore-bearing layer.—Mr. H. J. **Turner** exhibited several species of the lepidopterous genus Coleophora, and contributed notes on them.—Colonel Charles **Swinhoe** read a paper on tropical African Geometridæ in the national collection.—Mr. W. L. **Distant** communicated a paper entitled "Additions to a Knowledge of the Family Cicadidæ."—The president communicated a paper by Mr. G. F. **Leigh** entitled "Synepigonic Series of *Papilio cenea* (1902–3) and of *Hypolimnas misippus* (1904), together with Observations on the Life-history of the Former," and exhibited specimens to illustrate the same.—Mr. Edward **Saunders**, F.R.S., communicated a paper on Hymenoptera Aculeata from Majorca (1901) and Spain (1901–2).

Zoological Society, June 7.—Dr. F. DuCane Godman, F.R.S., vice-president, in the chair.—A communication from Lieut.-Colonel J. Malcolm **Fawcett** contained descriptions of ten species of butterflies, mainly from high elevations in the north-eastern Himalayas. Eight of them were new species or varieties.—Dr. A. G. **Butler** contributed a paper on seasonal phases in butterflies.—Captain Richard **Crawshay** read some notes on the prey of the lion, and exhibited some tips of porcupine quills that had been found buried in a lion's fore paws, together with the skull and skin of the lion.—Mr. F. E. **Beddard**, F.R.S., read the following papers, based on observations he had made in the society's prosectorium:—(1) Note on an apparently abnormal position of the "brephos" within the body of a skink; (2) contributions to the knowledge of the visceral anatomy of the pelagic serpents *Hydrus platyurus* and *Platyurus colubrinus*; and (3) on the presence of a parasternum in the lacertilian genus Tiliqua, and on the poststernal ribs in that genus.—A communication from Dr. E. A. **Goeldi** contained a description and an account of the habits of the rare rodent *Dinomys branickii*, Peters, specimens of which had recently been received at the Goeldi Museum, Pará.—A communication from Dr. C. **Satunin** contained a description of the black wild cat of Transcaucasia.—A paper was read from Mr. R. **Lydekker** containing the description of a new race of buffalo from East Central Africa. A second paper by Mr. Lydekker contained the description of a new species of deer from Ichang.—Dr. A. Smith **Woodward**, F.R.S., read a paper on two new labyrinthodont skulls which had recently been acquired by the British Museum. One was from the Triassic sandstone of Staffordshire, and the other from a formation of apparently the same geological age in Spitsbergen.

Geological Society, June 8.—Dr. J. E. Marr, F.R.S., president, in the chair.—The palæontological sequence in the Carboniferous Limestone of the Bristol area: A. **Vaughan**. The zonary divisions established are given in a table in the form in which they are finally set out. The corals and brachiopods are chosen as zone and subzone fossils, and genera are selected for zone-indices and circuli (or species-groups) for subzonal indices. To secure definiteness photographic figures are introduced. The relative acceleration of the two groups employed is not identical in different localities, and there is a small relative displacement of one group upon the other. The stratigraphy of all the important sections and isolated exposures in the Bristol area is dealt with. In each case is given a description of the position at which each zone or subzone is exposed and of its lithology, a list of the corals and brachiopods found, and a comparison with the same horizon in other parts of the Bristol area. The author claims that in the area with which he deals, his table of ranges is sufficient to enable any worker to zone any exposure with a considerable degree of accuracy.—On a small Plesiosaurus-skeleton from the White Lias of Westbury-on-Severn: W. F. **Gwinnell**. The matrix of the specimen corresponds

with the White Lias. The remains include more than twenty dorsal vertebræ, with spinous and transverse processes, lying in natural sequence. A pseudomorph of the spinal cord in calcite occurs also in position. Hitherto only single vertebræ or fragmentary bones of Plesiosaurus have been recorded from this horizon in Britain. At present, it has not been found possible to assign the fossil to any existing species.—The evidence for a non-sequence between the Keuper and Rhætic series in N.W. Gloucestershire and Worcestershire: L. **Richardson.** The section at Wainlode Cliff shows a transition in the "bone-bed," from a thin pyritic stratum, crowded with fish-remains, to a micaceous sandstone-bed, usually devoid of such remains and about a foot thick. This sandstone may be called the "bone-bed-equivalent." As the bone-bed can be traced in a single section laterally into a sandstone-bed devoid of those remains, the contemporaneity of the two developments is considered established. Above the main bone-bed the deposits of the Rhætic are persistent, but not below. Black shales are generally present below the bone-bed in Worcestershire, but in places there comes in a sandstone between it and the "tea-green marls." It is found that the greatest thicknesses of the Rhætic rocks under the bone-bed coincide with synclines, and the least thicknesses with anticlines. Thus the earth-pressures recognised in later times were probably at work at the close of the Keuper period. As the area once covered by the waters of the Keuper sea gradually sank, the Rhætic ocean slowly encroached upon the land-surface, and successive overlaps of the several infra-bone-bed deposits resulted.

Physical Society, June 10.—Dr. R. T. Glazebrook, F.R.S., president, in the chair.—Prof. H. L. **Callendar** gave a demonstration of the projection of the indicator diagrams of a petrol motor. The lantern-slides illustrated the working of the motor under various conditions, and were prepared to elucidate the nature of some of the defects which occur in practice. The motor itself was exhibited in action, with the indicator attached, and the actual diagrams were projected on the screen showing the changes of form as they occur when the conditions of running are changed. The motor employed was a Clement-Garrard cycle-motor, with 60 mm. bore and 70 mm. stroke. The engine, like most other internal combustion engines, works on the four-stroke cycle of operations—suction, compression, explosion, and exhaust—and runs at speeds varying from 2000 to 2500 revolutions per minute.—A model illustrating the propagation of an alternating current along a telephone cable, and a simple theory of the same: Prof. J. A. **Fleming.** Although the mathematical theory of the propagation of alternating currents along lineal conductors having capacity, inductance, resistance, and leakage has been developed by many writers in great fulness, the conclusions reached by them have not always been readily assimilated by practical engineers, and in some cases unsound theories have been put forward regarding the conditions limiting telephonic speech along wires. The present paper contains an account of a model (exhibited at the meeting) which has been constructed by the author for the purpose of explaining in a simple manner the physical meaning of the mathematical expressions which are reached in discussing the propagation of alternating currents along a telephone or telegraph cable. Mr. M. E. J. **Gheury** exhibited a gyroscopic collimator. The instrument is used in connection with an ordinary sextant, the observation being taken as with the sea horizon by bringing the image of an observed body into a field of vision, in which a horizontal grating of a special kind allows the observer to ascertain the direction of the true horizon.

Linnean Society, June 16.—Prof. W. A. Herdman, F.R.S., president, in the chair.—Mr. R. Brooks **Popham** sent for exhibition some calculi from the horse: two of very large size were obtained *post mortem* from a cart-horse employed in hauling coal; a third specimen from the same animal, on being broken, showed the nucleus to be a piece of coal, probably swallowed with its food. Another large stone was associated with many smaller, from a second horse—nearly one hundred in all. The specimens had been obtained from the stomach or intestinal canal of the animals.—Canon F. C. **Smith** sent for exhibition a handsome inflorescence of a scrambling shrub from Freetown, Sierra Leone, in habit resembling our native *Clematis Vitalba*. It proved to be *Rhynchosia calycina*, Guill. and Perr., which is widely spread in tropical Africa, reaching Rhodesia.—On variations in the arrangement of hair on the neck of the domestic horse: Dr. Walter **Kidd.** The author sought to test the validity of the theory that certain phenomena in the arrangement of hair in mammals are produced by mechanical causes. Numerous observations of the changes from a primitive type were figured and described. These changes, being shown to be congenital and of mechanical origin, were held to be instances of the inheritance of acquired characters.—An account of the Jamaica species of Lepanthes: Dr. **Rendle** and W. **Fawcett.**—On blaze currents of vegetable tissues: Dr. A. D. **Waller,** F.R.S. The author showed that these currents were symptomatic of the living tissue, and were not shown by dead organisms. In experimenting upon peas (*Pisum sativum*) the author mentioned the need of access to a garden, in order that the material might be gathered in proper condition, for certain experiences showed that garden produce obtained in the ordinary course from a market had suffered so much from bruising as to be worthless in these experiments.—On British freshwater Rhizopoda: J. **Cash.**—On the place of Linnæus in the history of botany: P. Olsson **Seffer.**

Royal Statistical Society, June 21.—Major P. G. Craigie, C.B., president, in the chair.—In a paper entitled "Observations on the Production and Consumption of Meat and Dairy Products," Mr. **Rew** summarised the conclusions of the committee of the society on both branches of their inquiry. The results suggested that the average consumption per head in this country was, of meat 121·8 lb., of milk 15 gallons, of cheese $10\frac{1}{2}$ lb., and of butter $18\frac{1}{2}$ lb. The meat included 56·8 lb. of beef and veal, $27\frac{1}{2}$ lb. of mutton and lamb, and 36·8 lb. of bacon and pork, but these quantities did not supply all the carnivorous demands of the population, as poultry, game and rabbits, as well as what butchers termed the "fifth quarter," were not included. In the case of milk, allowance should be made for the consumption of separated or skim milk, and also for condensed milk, neither of which was included in the average of 15 gallons. Reference was made to previous estimates, and it was suggested that the home production, both of meat and milk, had increased in recent years, though by no means sufficiently to keep pace with the growth of population. Some figures representing the estimated consumption in certain European countries, in the United States, and in Australasia, were given, and as the result of the comparison Mr. Rew observed that we appear to be well ahead of other European nations in meat consumption, but appreciably behind our American cousins, and remarkably less carnivorous than our Australasian brethren.

DUBLIN.

Royal Irish Academy, June 13.—Prof. R. Atkinson, president, in the chair.—Mr. George **Coffey** and Mr. R. Lloyd **Praeger** read a paper on the Antrim raised beach, in which they discussed the question of post-Glacial oscillations in northern Ireland, their extent and age. Their conclusions point to a submergence, of which the later part amounting to at least 20 feet, is early Neolithic in age, followed by an emergence of some 30 feet, which is later Neolithic, the only post-Neolithic movement being a slight submergence. The area affected by these movements embraces northern England, southern Scotland, and northern Ireland. Beyond this area, the Neolithic emergence appears to be absent.

PARIS.

Academy of Sciences, June 20.—M. Mascart in the chair.—Emanations and radiations: M. **Berthelot.**—On stability of equilibrium: Paul **Painlevé.**—On a new carbide of molybdenum, MoC: H. **Moissan** and K. **Hoffmann.** Molybdenum resembles tungsten and chromium in forming more than one carbide. The compound MoC described in the present communication is formed by heating molybdenum, aluminium, and lamp black together in the electric furnace. It is crystalline, harder than quartz, is attacked by acids with difficulty, except nitric acid, and is not decomposable by water.—The influence of discontinuity of muscular work on the energy expenditure: A. **Chauveau.**

—On the general theory of fundamental functions: W. **Stekloff.**—On the theory of spherical functions: Niels **Nielson.**—On the exceptional case of M. Picard and multiform functions: G. **Remoundos.**—On the construction of aërostats: Ch. **Renard.**—On the refractive powers of dissolved substances: approximate laws: C. **Chéneveau.** Generalisations of the experiments made by the author and by Dijken. It is shown that there is a constant ratio between the molecular refractive power of substances in solution and the square root of the molecular weight.—On the spectrum of calcium fluoride in the electric arc: Ch. **Fabry.** Most salts introduced into the electric arc give only the spectrum of the corresponding metal, but this is not the case with the fluorides of calcium, barium, and strontium. In this case, besides the spectrum of the metal, there is a brilliant band spectrum, which probably arises from the undecomposed fluoride. All the bands can be represented by equations of the form $N = B - Am^2$, in which N is the frequency, A and B constants, and m an integer.—The direct study of the transport of ultramicroscopic particles by the current: A. **Cotton** and H. **Mouton.** The motion of minute particles of colloidal silver has been studied under the microscope. Under the influence of an alternating current the particles are set in vibration, the period of which corresponds to the frequency of the alternating current.—The action of a magnetic field upon the n- and n_1-rays: Jean **Becquerel.** The action of the n- and n_1-rays upon feebly phosphorescent calcium sulphide is not produced when the bundle of rays passes through a magnetic field normal to the lines of force, but the action is transmitted without alteration parallel to the field.—An attempt at a photographic method for studying the action of the n-rays upon phosphorescence: E. **Rothé.** Owing to the difficulties experienced by many experimenters in obtaining definite results with a phosphorescent screen, it is obviously preferable to use an objective method if possible. An account is given of a photographic method.—Influence of the colour of luminous sources on their sensibility to the n-rays: C. **Gutton.** The sensibility of phosphorescent substances varies greatly with their colour. Calcium sulphide with violet phosphorescence is the most sensitive; the sulphides of the alkaline earths and sulphide of zinc, which possess a green phosphorescence, are less sensitive, and with sulphides possessing an orange phosphorescence no effect has been observed with the n-rays.—Remarks on a note of P. Villard on the magnetokathodic rays: H. **Pellat.**—On the electrostatic deviation of the magnetokathodic rays: Ch. **Fortin.**—The continuous registration of gaseous ionisation and of radio-activity by methods of loss of charge: Charles **Nordmann.** An electroscope is connected to the poles of a high voltage battery through a high resistance. Under the influence of the ionised gas the electroscope tends to lose a certain quantity per second, and this is balanced against the quantity coming in through the resistance from the battery. It is shown that the apparatus can be arranged to give the number of ions in the gas studied by a single reading.—On the properties of recently prepared gases: Eugène **Bloch.**—New researches on the cementation of ordinary and special steels: Léon **Guillet.**—On the production of isomorphous mixtures of lime and lithia: P. **Lebeau.** A mixture of the carbonates of lime and lithium decomposed by heat in a vacuum leaves a well crystallised residue of the mixed oxides, the composition of which depends on the temperature and duration of heating. The formation of mixed crystals of lime and lithia renders probable a cubic form for the latter substance.—The electrolytic separation of nickel and zinc: MM. **Hollard** and **Bertiaux.** In the presence of ammonium nitrate the nickel only is deposited. Experimental data are given showing that the separation is complete.—The alloys of magnesium with aluminium and antimony: Hector **Pécheux.**—The formation of dimethylisopropylcarbinol in the reduction of acetone: G. **Denigès.** In addition to isopropyl alcohol and pinacone, the usual reduction products obtained from acetone by reduction with sodium, the author has been able to isolate the above tertiary alcohol. The yield is small.—Syntheses in the pentamethylene series; the diamylene of pentane-diol: 1:5-diiodo- and dibromopentane: J. **Hamonet.**—The condensation of phenols and aromatic amines with benzylidene-aniline: Charles **Mayer.**—On the normal presence of formaldehyde in products of combustion and in smoke: A. **Trillat.** A small amount of formaldehyde is always formed in all combustions, even of hydrocarbons. The author regards this as a confirmation of the results of A. Levy and Henriet on the presence of traces of formaldehyde in atmospheric air.—Addition compounds of rosaniline salts; their dissociation, thermochemistry, and constitution: Jules **Schmidlin.**—Researches on the azo colouring matters derived from 2:2-dinaphthol: Emm. **Pozzi-Escot.**—On the existence of an oxidising-reducing diastase in plants, and the conditions of its action: J. E. **Abelous.**—On the classification of the Anthozoa: Louis **Roule.**—Parallel adaptation of the host and parasite under the same conditions of existence in certain Lepidoptera and their parasitic Diptera: J. Kunckel **d'Herculais.** —On the early state in some palms: C. L. **Gatin.**—On the geology of the neighbourhood of Barcelona, Spain: Jaime **Almera** and Jules **Bergeron.**—The Coal-measures in the north of Africa: Ed. **Bureau.**—The molecular weight of glycogen: Madame Z. **Gatin-Gruzewska.** The lowering of the melting point observed by Sabanejew for glycogen was due to the presence of impurities, since determinations on the purified substance give a scarcely appreciable lowering. The molecular weight of glycogen from these determinations cannot be lower than 140,000.—Studies on the action of maltase. Constancy of the ferment: influence of the products of the reaction: Mdlle. Ch. **Philoche.**—Contribution to the study of the formation and elimination of urea in man: H. **Labbé** and M. **Morchoisne.**—On the action of blood rendered hepatotoxic by intraperitoneal injections of the nucleoproteids of the liver: H. **Bierry** and André **Mayer.**—On the progressive ripening of cheese: M. **Lindet** and Louis **Ammann.**—Oceanography of the region of the Azores: M. **Thoulet.**

CONTENTS.

THURSDAY, JULY 7, 1904.

THE HARRIMAN ALASKA EXPEDITION.

Alaska. Vol. iii.—Glaciers and Glaciation. By G. K. Gilbert. Pp. 231; 18 plates and 106 text figures. Vol. iv.—Geology and Palæontology. By B. K. Emerson, C. Palache, W. H. Dall, E. O. Ulrich and F. H. Knowlton. Pp. 173; 32 plates and 18 text figures. (New York: Doubleday, Page and Co., 1904.)

IT is now nearly two years since we noticed in our pages (NATURE, vol. lxvi. p. 176) the two handsome volumes which were the first-fruits of the scientific holiday cruise in Alaska carried out in the summer of 1899 by a party of competent observers through the liberality of Mr. E. H. Harriman. Two further volumes of the series are now before us, one recording the observations made on glaciers and glaciation during the expedition, and the other dealing with the geology and palæontology of the places visited. Though necessarily of more restricted interest than the two first volumes, which dealt with general and varied topics, these books are scarcely one whit behind their predecessors as specimens of the printer's art, except in the matter of coloured plates. Profusely illustrated, well printed on good paper, and tastefully bound, it is evident that no expense has been spared in their production, and rarely do we find technical writings bedecked in such garb. The toned plates are beautifully reproduced, but the line drawings from photographs, which constitute most of the text figures, appear to have suffered to a certain extent from the very excellence of the paper, and would probably have shown to better advantage on the heavy smooth-surfaced product that we growl over so often in American books.

Neither volume is monographic for its subject, but while giving many references to previous literature and to data accumulated by foregoing explorers, deals mainly with the direct results of the expedition. In fact, the books are essentially a series of "papers" on the geology of Alaska, and the subject-matter is treated accordingly.

The first of these volumes (vol. iii. of the series) consists of observations on the glaciers visited by the party, and on the general glacial phenomena of the region, Mr. G. K. Gilbert acting as recorder in this subject. In his lucid descriptions of the existing glaciers and in his able discussion of some of the problems connected with their past history, Mr. Gilbert presents much that is of extreme interest to the glacialist, though the opportunities for personal study were mainly confined to the lower ends of glaciers that reach nearly or quite to tidal waters. In all cases, care is taken to give details and illustrations from dated photographs, so that future observers will be enabled to determine the movement of the ice-front. In many instances, past records were in existence which permit the modern changes in the length of the ice-rivers to be discussed. Curious discrepancies between the conditions in different parts of the country are recognised, for while some glaciers are in rapid retreat—*e.g.* the Muir, which when visited in 1899 was more than a mile and a half shorter than it was nineteen years previously—others had recently advanced.

"The most conspicuous fact brought out by the comparison of local histories is that they are dissimilar. Nevertheless, there are limited resemblances. The Glacier Bay and Disenchantment Bay histories agree in including a great retreat, occupying more than a century. The Port Wells and Grewingk histories agree in a moderate retreat occupying something less than a century. The La Perouse and Columbia histories agree in a present condition of maximum glaciation probably preceded by an important minimum" (p. 104).

The possible cause of these variations is discussed; and although no definite conclusion is reached, it is suggested "that the combination of a climatic change of a general character with local conditions of a varied character, may result in local glacier variations which are not only unequal but opposite" (p. 109).

The Columbia and La Perouse glaciers in their recent advance have invaded a mature forest-growth which had established itself near their margins. Most instructive to the glacial geologist are the illustrations and descriptions of the "push-moraines" of bouldery till full of crushed trees—in one case "not only tree trunks and branches but folds of peaty soil" (p. 77)—which, by a slight recent retreat of the ice, are left open to investigation along the devastated fringe of the forest. In looking at these pictures one might imagine that some gigantic wild boar had been uprooting the ground. Noteworthy, too, are the stream-built "waste plains" of coarse gravel which overspread the valley-floor in cases where the glacier does not reach quite to the sea, as described and illustrated in the instances of Hidden Glacier (p. 53) and Grewingk Glacier (p. 94).

It is mentioned that in 1899, soon after the visit of the expedition, Glacier Bay was choked up with floating ice, apparently due to the disintegration of the tidal ice-fronts by an earthquake shock. And since then, until the time of writing, it had been impossible for steamers to approach within several miles of the Muir Glacier.

The effect of ice-falls from the ends of tidal glaciers was observed to produce waves sufficient to erode the coast in places where wind-waves could not form; and it is suggested by Mr. Gilbert that we may thus explain the clear outlining of the shores of some glacial lakes the area of which seems to have been insufficient to produce important wind-waves.

In dealing with the Pleistocene glaciation (chapter ii.), Mr. Gilbert discusses the origin of the "hanging valleys" so abundant in this region, and accepts the view that the discordance of level between the trunk and tributary valley is in most cases due to the deeper glacial excavation of the main trough.

"It [the hanging valley] is a conspicuous earmark of the former presence of glaciers; and it helps to a conception of the magnitude of Pleistocene glacial erosion" (p. 115).

The grounds on which this assumption is based are fully stated and illustrated. Great stress is laid upon

the excavating action of ice by the process of "plucking," in which "blocks of bed-rock, being partly surrounded by the ice, are forced from their bearings and rolled or slidden forward" (p. 203). Evidences of marine submergence reaching up to at least 500 feet above present sea-level are described (p. 168), and it is surmised that local uplift may have taken place in the neighbourhood of the high mountains at a period later than the chief Pleistocene glaciation (p. 173).

The observations, admittedly scanty, on the coasts of Bering Sea, though indicating local glaciers of considerable magnitude, "seemed inconsistent with the theory of a continental glacier in the Bering Sea region" (p. 192).

The chapter (iii.) on "General Considerations as to Glaciers" formulates the elementary comparison between rivers of ice and rivers of water in the manner which American geologists have made customary. It contains also, among other suggestive matter, a novel discussion as to the effect of water in buoying up the ends of "tidal glaciers" when not deep enough to float them. The conclusion is reached "that there is no important difference, as respects pressure on the rock bed, between a glacier resting on the land and one which is partly bathed by the waters of a fiord" (p. 216), with the further significant deduction that the depth to which glacial troughs have been excavated is not demonstrative of a relatively low base-level at the time of their excavation (p. 217).

We have scanty space for the notice of the second of the volumes before us (vol. iv. of the series), which, however, is for the most part severely specialised. It consists of more or less independent contributions by several authors.

Prof. B. K. Emerson gives a general account of the geology of the places visited, with petrographical notes by Dr. C. Palache. The rocks described are mostly much altered by dynamic and thermal metamorphism, so that their age is often doubtful. They include old-looking gneiss, possibly pre-Cambrian; Carboniferous; Triassic or early Jurassic ("the Vancouver Series"); radiolarian chert perhaps Jurassic or early Cretaceous; and newer volcanic rocks.

Dr. C. Palache contributes some notes on the geology of the famous Alaska-Treadwell Mine of Douglas Island; a list of the minerals collected by the expedition; and a paper on the rocks of the neighbourhood of Chichagof Cove, in the Alaskan peninsula, where beds containing abundant fossils of Lower Eocene age were discovered, a period not previously recognised in Alaska. These fossils, which include our familiar *Venericardia planicosta,* are described and figured in a separate paper by Dr. W. H. Dall, who also describes some Pleistocene shells from Douglas Island.

Mr. E. O. Ulrich deals with the fossils of the Yakutat formation, which consist mainly of very curious casts, supposed to be fucoidal. A large number of these markings are named, described and figured, the beds containing them being assigned, on somewhat slender evidence, to early Jurassic, probably Liassic, times.

A collection of fossil plants of Upper Eocene age from Kukak Bay, on the Alaskan peninsula, forms the subject of the contribution by Mr. F. H. Knowlton, with which the volume closes. Of the twenty-six forms represented in this collection, nine are described as new to science.

G. W. L.

JOSEPH PRIESTLEY.

Memoirs of Dr. Joseph Priestley. Written by himself (to the Year 1795), with a Continuation to the Time of his Decease by his Son, Joseph Priestley. Reprinted from the Edition of 1809. Centenary Edition. Pp. 132. (London: H. R. Allenson, 1904.) Price 3*s.* net.

THE story of the origin and history of this little book may be told in a few words. The greater portion was composed by the subject of it in the year 1787, when at Birmingham as minister of the New Meeting. Priestley's tenure of this office was rudely interrupted by the shameful and disastrous riots of July, 1791, when his house and laboratory, and much of his apparatus and library, were destroyed by the mob. Although many of his books and papers were burnt or otherwise made away with, the autobiography escaped destruction, and was ultimately recovered. Some years afterwards, whilst at Northumberland, in Pennsylvania, whither he removed in 1794, he resumed the story of his life, bringing it down to March, 1795, when he had completed the sixty-second year of his age. Although he lived nine years more, for the most part in fairly good health, it would appear that he added nothing to his account of himself, and it was left to his eldest son to continue his biography to the time of his death, and to see the work through the press. The first edition of the "Memoirs" was published by Johnson, of St. Paul's Churchyard, a staunch friend of Priestley's, by whom, indeed, the greater number of his works—educational, theological, and scientific—were issued. It was reprinted in 1833, on the occasion of the centenary of his birth, and it is again reprinted in commemoration of the centenary of his death.

The present edition differs from its predecessors in several particulars. It is not quite so sumptuously printed as that of 1806. It resembles the edition of 1833 in containing illustrations. In the book before us, however, these are more numerous and more interesting, from the circumstance that the reader is enabled to see in some measure what manner of man physically Priestley was at various periods of his career. Unfortunately the illustrations hardly do justice to the originals, and as process reproductions leave much to be desired. The frontispiece is taken from a copy of Opie's well known portrait, now, we believe, in the Manchester College, Oxford. The second portrait is a poor and partial reproduction of Fuseli's picture, painted for Johnson, the publisher, and one of the very few portraits which that painter made directly from a sitter. The original work was a full-length figure, and is interesting as showing Priestley at the period of his greatest scientific activity. It is interesting, too, as affording material for the statue by Stephens in the Oxford Museum, of which we have a picture in the book. The third portrait is

by Artaud, a painter largely employed by the Nonconformists of his day, and represents Priestley as he appeared at the time of his leaving England for America. The last portrait is by an American artist, Stewart, and shows Priestley without his wig, and in the costume he adopted at Northumberland. We have in addition a reproduction of Williamson's statue erected in Birmingham, and unveiled by Huxley in 1874 on the occasion of the centenary of the discovery of oxygen. Lastly, there is a copy of Drury's fine statue which Leeds owes to the munificence and public spirit of Colonel Harding.

The Rev. Mr. Freeston, who is responsible for the issue of the present edition, is, no doubt, a great admirer of Priestley as one of the chief apostles of Nonconformity, as the sturdy champion of Unitarianism and the resolute defender of free inquiry and liberal thought, and this circumstance may account for the fact that, in his selection of the illustrations, the scientific side of Priestley's activity receives practically no recognition. Dr. Taylor, of Norwich, who became head of the Warrington Academy, was no doubt an eminent divine, but his connection with Priestley was of the slenderest. Dr. Andrew Kippis was of some assistance to him at times, especially in the earlier period of his career. Dr. Price, whom he succeeded at Hackney, and the Rev. Mr. Theophilus Lindsey were almost life-long friends, and no doubt exercised considerable influence on his fortunes. But so did Josiah Wedgwood, James Watt, whose association with Priestley gave rise to the famous Water Controversy, Matthew Boulton, Keir, Withering, and other members of the celebrated Lunar Society. There can be little doubt that Priestley's career as a natural philosopher, and, indeed, as a political writer and reformer, was largely the result of his connection with Franklin, for whom he had the greatest admiration and affection, and to whom considerable reference is made in the "Memoirs." Lord Shelburne, too, with whom Priestley spent some of the most fruitful years of his busy life, afforded him, in ample measure, time, money and opportunity for the prosecution of his work on pneumatic chemistry, and thereby contributed to lay the foundation upon which his fame largely rests. But although portraits of these persons are at least as accessible as those of the worthy Nonconformist divines mentioned above, and should, in all fitness, appear in any edition of Priestley's "Memoirs" in which portraits of his friends and co-workers are made a distinctive feature, they are conspicuous by their absence.

The reproduction of the view of Priestley's birthplace at Fieldhead, near Birstall, presumably made from Mr. Buckton's photograph, is interesting and pictorially unobjectionable, but that of the Nantwich Meeting House, where Priestley officiated for about three years, is simply hideous. The only thing that can be said in its favour is that it is at least as meritorious as the architectural character of the building it seeks to depict. Nor is the view of the Old Academy at Warrington much better. Priestley was, no doubt, familiar with the old building on the banks of the Mersey, although his connection with it was as slender as his association with its first head, Dr. John Taylor. Most of Priestley's life as a tutor at Warrington was spent in the New Academy, situated some distance from the building represented, and which, by the way, the author of the "History and Present State of Electricity" and of the "Essay on the First Principles of Government, and on the Nature of Political, Civil and Religious Liberty" would certainly not have recognised as here shown, mainly by reason of the imposing statue of the stalwart Cromwell and the large incandescent electric lamp which bulks so largely in the foreground. The fact is, the view represents the Old Academy as it exists to-day as the home of the Warrington Society, to the praiseworthy zeal and public spirit of which the old house has been rescued from the oblivion which was overtaking it.

We have no inclination to be hypercritical, but it is surely desirable that in the re-publication of a work which in its way may be reckoned as one of the classics of scientific biography, and is now brought out to commemorate the centenary of the death of its illustrious author, some effort should have been made to make the appearance of the book more worthy of its subject and of the occasion which has led to its re-issue.

T. E. THORPE.

A LADY ENTOMOLOGIST.

Eleanor Ormerod, LL.D., Economic Entomologist. Autobiography and Correspondence. Edited by Prof. Robert Wallace, Professor of Agriculture and Rural Economy in the University of Edinburgh. With portraits and illustrations. Pp. xx+348; plates xxx; text illustrations 76. (London: Murray, 1904.) Price 21*s.* net.

THE name of Eleanor Anne Ormerod will long be remembered for her unflagging industry and long-continued devotion to practical entomology, not surpassed in their own lines of research by Caroline Herschel and Mary Somerville, with whom she may most fittingly be compared. There can be no more fitting opportunity than the present to recall her services both to science and the world at large, when the Linnean Society (formerly so exclusive that ladies who contributed papers were not even admitted to be present when they were read) has just thrown open its full membership to women. The Entomological Society was never so exclusive; and at one time Miss E. A. Ormerod was one of the most regular attendants at the meetings, sometimes accompanied by her sister and fellow-worker, Georgiana E. Ormerod, and more rarely by some other lady friend.

By far the most interesting portion of this volume is the autobiography (occupying chapters i. ii., iv.–x.). Next in importance are chapter iii., by Miss Diana Latham, referring to Miss Ormerod's early life, and chapter xi. by the editor completing (all too briefly) the biographical sketch of Miss Ormerod's life. A very full account is given of her family, surroundings and education, with reminiscences of coaching days, the Chartist rising, and other matters which look like ancient history now, besides occasional geological and

archæological notes. Miss E. A. Ormerod was the youngest of a family of ten children, and was born on May 11, 1828, and she died after a long illness on July 19, 1901, after a busy and useful life, as happy, we may well believe, as that of Miss North or Miss Cobbe.

Natural history runs in families, and besides the two sisters, Eleanor and Georgiana, one of the brothers, Dr. E. L. Ormerod, has also left a worthy entomological record behind him in his valuable work on "British Social Wasps."

Among Miss Ormerod's accomplishments was a knowledge of Russian. It would have been interesting if we had been told how she came to study a language still so little known in England.

Miss Ormerod does not appear to have specially interested herself in entomology until 1852, and it was not until 1877 that she commenced the great series of reports of observations on injurious insects, the twenty-fourth and last of which was only issued in 1900, the year before her death, so that she may be said to have died in harness, though towards the end she found herself compelled by failing health gradually to decrease her entomological activities in other directions also. The most pleasing portrait of her in the book (taken from the oil painting in the University Court Room, Edinburgh) represents her in her University costume as the first woman hon. graduate of the University of Edinburgh, an honour as much to the University as to herself, and more gratifying to her than any other acknowledgment of her entomological work could have been. The title was conferred upon her on April 14, 1900. Her sister Georgiana predeceased her in 1896.

At the time when Miss Ormerod commenced her work in agricultural entomology much had been done by Westwood and Curtis to pave the way; but the few books on the subject were either costly or little known, and no popular interest was felt in the matter.

Miss Ormerod, however, by her reports, books and lectures, revolutionised all this, and effected a work equivalent to that of Riley in America, and the importance of agricultural entomology is now universally recognised, from the Government to the School Board. She was also a good practical meteorologist, and a fellow of the Royal Meteorological Society.

But it is much to be regretted that Miss Ormerod did not live to complete her autobiography on her own lines, and we cannot congratulate the editor on the manner in which he has performed his task. As he states in the preface, "Had the book been produced on the original plan, it was proposed to name it, 'Recollections of Changing Times.' It would have dealt with a number of subjects of general interest, such as the history of the Post Office, early records of floods and earthquakes, as well as newspapers of early date. The introduction of Miss Ormerod's letters to a few of her leading correspondents was made necessary by the lack of other suitable material. The present volume is still mainly the product of Miss Ormerod's pen, but with few exceptions general subjects have been eliminated, and it forms much more a record of her works and ways than it would have done had she been spared to complete it."

Surely at the present day specialism is so great, though so unavoidable, an evil, that the wilful elimination of everything but entomology from the chapters not actually written and edited by Miss Ormerod herself is equally unfair to herself and to her admirers. Had her correspondence been utilised with her reports to compile an abstract of entomological observations supplementary to those contained in her more permanent manuals the work might have been made a more worthy memorial of her; but instead of this two-thirds, at least, of the volume is composed of letters to various entomological correspondents without any sort of order or classification except by correspondents' names, and consists of disjointed observations on insects, and references to matters like the exchange of publications, of no real permanent interest or consequence, even to entomologists. Half-a-dozen letters selected to show Miss Ormerod's epistolary style would have been amply sufficient. The only interesting portions of this section of the work (except the few letters addressed, chiefly to the editor, on personal matters like the Edinburgh degree) are the numerous illustrations of insects reproduced from Miss Ormerod's reports, &c.

The early part of the work and the illustrations render the book useful and interesting; of the latter part we can only say that it is one of the most glaring instances we have ever seen (and we have seen sufficiently bad ones before) of how *not* to edit a biography.

SOCIAL CONDITION OF ANTHRACITE MINERS.

Anthracite Coal Communities. By Peter Roberts, Ph.D. Pp. xiii+387. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1904.) Price 15*s*. net.

THE great strike of 1902, which cost 20,000,000*l*. and led to the intervention of the President of the United States, induced Dr. Roberts to make an exhaustive study of the 630,000 persons deriving subsistence from the production of the anthracite collieries of Pennsylvania, and his book should be studied by all interested in the evolution of industrial society. The coalfields are situated in the north-eastern portion of Pennsylvania, and consist of scattered deposits of anthracite covering an area of 480 square miles. The mining population represents some twenty-six different races, one-half being Slavs. Anthracite mining is about eighty years old.

In the first fifty years of the development of the industry the United Kingdom and Germany furnished the labour required. During the past twenty-five years the Slav nations have done so. Immigration into the coalfields has now virtually ceased. The present population is amply sufficient to furnish the necessary labour for the maximum tonnage that the collieries can produce. Conditions in the industry are not such as to attract labour of a high grade, and the high birth-rate of the Slav population will more than supply the labour needed in an industry that will necessarily soon be declining.

The characteristics of the Slav population are depicted by the author in lurid colours. The Slavs are, he asserts, clumsy, ignorant, drunken, superstitious, unclean and brutal. At the same time the Slav nature is good material to work upon. As the Slav comes in contact with Anglo-Saxons and learns their ways, his wants are increased and his tastes refined. The unsavoury details of squalor and vice among the Slav miners are certainly not understated by the author, who has naturally no sympathy with the ideas and aspirations of a people who, by adhering to their language and customs, remain unassimilated after years of residence in the United States. Similar statements are often made regarding the Slav immigrants in the coalfields of Scotland and of Westphalia. Probably the Slav colliers of Pennyslvania are not more debased than the mining populations of many of the European coalfields. If they are, the responsibility must rest largely with the coalowners, who provide habitations where self-respect and decency are unattainable luxuries.

The author's gloomy views regarding the social condition of the anthracite communities cannot be accepted without reserve. They are certainly not in accord with the views of the Anthracite Coal Strike Commission, who found that the social conditions obtaining in the communities made up largely of coalworkers were good, and that the number and character of the schools accessible in all these communities were fully up to the American standard. The number of churches in proportion to the population was rather above the average, and the opportunities generally for instruction appeared to be adequate.

The work is illustrated by twenty-eight half-tone plates, most of which are excellent, and there is a long bibliography of works consulted. The quotations in French, being printed without accents, are difficult for the ordinary reader to understand, and in one quotation, "Ellis il font diaque nuit," it is not apparent what language is used. B. H. B.

OUR BOOK SHELF.

Elements of Water Bacteriology. By Samuel Cate Prescott and Charles-Edward Amory Winslow. Pp. x+162. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd.) Price 5s. 6d. net.

THIS little volume is practical in its conception, and is concise in treatment. It, of course, presupposes a sound knowledge of general bacteriological methods, but the authors have undoubtedly produced a manual for laboratory use which will be of value to all intelligently engaged in the examination of water. It is up to date in the various methods described, and thirty pages are devoted to a careful index of the contents, a list of memoirs referred to in the text, and the names of authors. Perhaps the most interesting feature in the book is the "change in front," so to speak, which it indicates some water-bacteriologists are making in regard to the relative importance of the presence of typhoid and colon bacilli respectively in water. A third of the letterpress is devoted to the *Bacillus coli communis*, its detection and its significance in water, whilst the typhoid bacillus, so long the *bête noire* of sanitarians, is disposed of in a few pages. The attitude of, at any rate, American authorities is effectively summed up in the following paragraph:—

"On the whole it seems that since a positive result is always open to serious doubt, and a negative result signifies nothing, the search for the typhoid bacillus itself, however desirable theoretically, cannot be regarded at present as generally profitable."

So, because the typhoid bacillus is difficult to find and the detection of specific organisms is being clamoured for in the estimation of the bacterial quality of a water, refuge is taken in the more easily discoverable and well-nigh ubiquitous colon bacillus, or its allied forms.

It will be interesting to watch the progress of opinion on this colon-standard of water-purity in the light which it is hoped further researches may be able to throw on the detection and significance of specific bacteria in water.

The Chemistry of Coke. By W. Carrick Anderson, M.A., D.Sc. Second edition. (Glasgow and Edinburgh: Hodge and Co., 1904.) Price 5s. net.

THIS little volume, which has reached its second edition, contains much practical information about the chemistry and chemical analysis of coal and coke which should be useful to scientific makers of coke.

But apart from its practical side, the book would justify its publication if it served the single purpose of showing how scientific method may be applied to the problems of a relatively simple industry. That different coals of the same composition, or *isomeric coals*, as the author calls them, behave quite differently on coking is well known. This must, of course, arise from the presence of different chemical constituents. Perhaps it would have been wiser to remain content with the statement (p. 64) that "so long as the composition of coal is unknown the peculiar internal reactions of coking will assuredly remain shrouded in obscurity" than to hazard the suggestion (p. 60) that "in coking, side-chains as well as the central part or radicle reacts."

The absence of any reference to the relation of composition to by-products seems a curious omission when, as the author himself says, "the manufacture of coke without recovery of by-products is to-day frequently regarded as scarcely any longer a payable industry."

The writer would like to offer the suggestion that a careful microscopic examination of coal, which has been found so useful in other directions, might lead to interesting information both as to coking qualities as well as the nature of the by-products of different varieties of coal. Perhaps this method of investigation has already been tried and found wanting. J. B. C.

Praktischer Leitfaden der Gewichtsanalyse. Zweite Auflage. By Paul Jannasch. Pp. xvi+450. (Leipzig: Veit and Co.) Price 8 marks.

A SECOND edition of Prof. Jannasch's well known book treating of gravimetric analysis has now appeared, and contains considerable additions of new matter. It is obvious, even from the most cursory examination, that the book differs from most of its class in that it is in no sense a compilation of old and often obsolete methods.

Prof. Jannasch is well known as the author of many new methods in analytical chemistry, and the results of his own work and that of his pupils have been made great use of in preparing the present volume.

The contents of the book are divided into nine sections, each of which deals with analyses of a particular type; thus, starting from the determination of the constituents of simple salts in the first, the second treats of the analysis of simple alloys, whilst the third, fourth, and fifth sections deal with the quantitative separation of the various metals one from another. By far the greater number of the processes recommended for these separations are those with which the author's name is connected, involving the use of hydrogen peroxide, hydroxylamine, and hydrazine,

The sixth and seventh sections contain instructions for mineral analysis, and one is struck by the very complete account given of methods by which the decomposition of the mineral is effected by heating in a current of gas, *e.g.* oxygen, hydrochloric acid, or bromine. The eighth section is taken up with silicate analysis, whilst the concluding section gives an account of the estimation and separation of the halogens and of many other analyses which do not naturally find a place in the earlier portions of the work.

Although it is clear that the author has taken great pains in the preparation of his book, it may be questioned as to whether the selection of exercises has been uniformly judicious, and as to whether the author's own processes do not occupy a too prominent position, so leading to the exclusion of standard methods of analysis with which every student should be familiar. For example, the author's process for the separation of manganese and zinc by means of hydrogen peroxide in alkaline solution, although found unsatisfactory by other investigators, is fully described to the practical exclusion of the more usual method. The same criticism applies to the larger proportion of the other "hydrogen peroxide separations" which here figure so largely. Again, in the section dealing with silicate analysis, the author's methods of decomposition, especially the one employing boric anhydride, are given at great length, whilst the ordinary method of alkali-carbonate fusion, which is constantly employed both in technical and scientific analyses, is given in a not very happily modified form, and in a subordinate position.

Although the book presents very many excellent features, and should, when used in conjunction with other works, be of great value, it is hardly considered likely that a student who derives his information solely from this source would possess a competent knowledge of the *general* methods of analytical chemistry.

H. D. D.

Practical Slide Making. By G. T. Harris, F.R.P.S. Pp. 134. (London: Iliffe and Sons, Ltd., 1904.) Price 1s. net.

NEARLY every photographer at some time or another makes his own lantern slides, and so numerous are the methods available, and so varied are the results that can be obtained, that another handbook on the subject is very welcome. In these pages the author successfully attempts to supply trustworthy information on the subject in a concise form, describing the best known methods for obtaining these transparencies. He lays stress on the great efficiency of some of the older processes, and with the hope that they may be revived he includes them in this book. The first two chapters deal with the apparatus for exposing the plate, and the remainder treat of the development by the several methods described, and of the various other manipulations required before the slide can be considered properly finished. No pains seem to have been spared to obtain accuracy in the formulæ and to render clear the methods of procedure, so that the book forms a trustworthy guide.

Botany Rambles. Part ii. *In the Summer.* By Ella Thomson. Pp. 130. (London: Horace Marshall and Son, 1904.) Price 1s.

THE young learners for whom this little book is intended are urged persistently to see for themselves, by examining plants, that what is told them in the lessons is true. They are instructed in simple language how to set about this work of verification and are urged to make use of their own eyes to find out additional facts for themselves. It is evident that the writer understands children and knows how to arrest their interested attention.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Exradio Spectrum.

FROM a private communication from Mr. Baxendall, I learn that he has noticed the following correspondences between the spectrum of the emanation from radium (exradio) and the spectra of "bright line stars" (Campbell, *Ast. and Ast. Phys.*, vol. xiii. p. 468):—

"Exradio."	Bright Line Stars (Campbell).
5805	5813
5595	5593*
4690	4688
4650	4652
4630	4633

With the exception of 5593*, these stellar lines are all strong and characteristic. Another of the exradio lines, 5137, may correspond with 5135.

I am very ignorant of stellar spectra, and send this note merely to direct attention to a possible correspondence.

University College. WILLIAM RAMSAY.

The Occurrence of Radium with Uranium.

A LITTLE time back, Mr. B. B. Boltwood published in this Journal (May 26, p. 80) a preliminary notice of an investigation of the ratio of uranium to radium in various minerals. I have for some time been engaged in a similar investigation, which, though the results are not yet matured, seems to be leading to the conclusion that this ratio is constant, as in Mr. Boltwood's experiments. An interesting case is the mineral torbernite, or copper uranite. This mineral forms transparent green tetragonal crystals the composition of which is accurately represented by the formula $CuO.2UO_3.P_2O_5.8H_2O$. The substance dissolves easily in sulphuric acid, forming a perfectly clear green solution. This solution, when boiled, gives the radium emanation, and the quantity of emanation produced in one day is about the same as that yielded by the same weight of Joachimsthal pitchblende. The percentage of uranium is also about the same. If the radium in this mineral has been produced since the formation of the mineral (and the recent quantitative experiments of Sir W. Ramsay and Mr. Soddy on the absolute rate of production of the emanation seem to make that certain), there is practically no choice as to what the parent substance should be. Uranium is the only candidate. The great complexity of most of the radio-active minerals may make it difficult to obtain conclusive evidence by studying them. But here there seems to be no alternative but to conclude that uranium is the parent. R. J. STRUTT.

Residual Affinity.

SIR OLIVER LODGE's highly suggestive letter (June 23, p. 176) will be welcome to the many chemists who have been endeavouring to interpret chemical phenomena in terms of the electronic theory of the physicist. The proposition that the "Faraday tube" may be subdivided would appear to be capable of being widely applied in connection with many of the most interesting phenomena of chemistry. Thus not only would the existence of water of crystallisation and the formation of so-called molecular compounds be thereby brought into line with the more typical manifestations of valency, as pointed out in Sir Oliver's letter, but it would appear that it may possibly enable the hitherto conflicting hydrate and dissociation theories of solution to be harmonised. Thus in the case of an electrolyte such as sodium chloride, we should in the dry state regard the sodium atom united to the chlorine atom by means of a Faraday tube or bundle, as it may more appropriately be designated, the union leading to the great stability of the compound as such. On the addition of water, however, some of the constituent fibres or strands of the bundle become deflected in such a way that the sodium

and chlorine atoms become respectively combined with water. With sufficient water present the original union between the sodium and chlorine atoms will become entirely severed, the Faraday bundle starting with its positive extremity on the sodium atom will terminate at its negative end *by means of a plurality of strands on a number of water molecules*, and similarly the Faraday bundle emanating by its negative extremity from the chlorine atom will terminate at its positive end in a plurality of strands also on a number of water molecules. In such a solution we should thus have independence of the sodium and chlorine atoms, or the phenomenon of ionisation. In such a solution, moreover, the union between sodium and chlorine would be entirely abolished through the complete diversion of the strands of the Faraday bundle formerly uniting them, whilst the union between the oxygen and hydrogen of the water molecules would be but slightly weakened owing to only a small fraction of the total number of strands in the bundles uniting the oxygen and hydrogen in each molecule being diverted by the sodium and the chlorine. The dissociation into its ions of an electrolyte on solution in water would thus be the consequence of the antecedent hydration of the ions.

Some of the colour changes attending the attachment of water of crystallisation may be interpreted in the same way. Thus anhydrous copper sulphate is colourless, whilst the crystallised salt containing five molecules of water is blue. The direct union of the copper atom by means of two Faraday bundles with the SO_4-group leads to the production of a colourless compound, whilst by the diversion of the strands of these bundles, through the attachment of five molecules of water, the copper atom and the SO_4-group become severed, and the blue colour characteristic of the copper ion makes its appearance.

According to this view solution should always be attended by the weakening of the union between at least one pair of bonds in the molecule of the solute owing to the diversion of at any rate some strands of the bundle or bundles, and such loosening is betrayed in the greater chemical reactivity of substances in solution.

Similarly in catalytic phenomena, the catalytic agent may be regarded as diverting some of the constituent strands of bundles, and the action of water in effecting ionisation, *i.e.* complete diversion of bundles, would thus appear as an extreme case of catalysis, leading to such an acceleration of the velocity of reaction between electrolytes that reactions between ionised electrolytes are practically instantaneous.

It is needless to say that this is merely a preliminary and very imperfect attempt to apply the electronic theory to a few of the most familiar and important chemical phenomena. Sir Oliver Lodge's suggestion with regard to the electrical interpretation of valency and bonds is indeed so luminous and stimulating that it should provoke the careful review of chemical facts by the light of this new conception of the possibility of an indefinite number of different grades of chemical union, of which the union by chemical bond, hitherto the only one generally recognised, is to be regarded merely as an extreme case.

Birmingham, June 27. PERCY F. FRANKLAND.

Science in the Common Examination for Entrance to Public Schools.

IN the interests of education, may I ask you to find room in your columns for the enclosed copy of the science paper recently set in the above examination? The average age of the candidates may be taken as about thirteen years. Comment is almost superfluous. The effect, whether intentional or not on the part of those who set the questions, of such an examination paper must be to discourage science in the preparatory schools. No boy of thirteen years of age could or should be expected to answer more than a very small portion of so advanced a paper. If headmasters of preparatory schools are led to imagine that this is the kind of thing that is expected of their pupils, in very despair they will be forced to abandon science entirely, and fall back upon its alternative in this examination—Latin verse.

This common examination has now been held for the first time, and it is important that an emphatic protest should be raised without delay. If the science paper is allowed to be of this unreasonable character, the subject will receive a set-back that will go far towards undoing all that has been tardily achieved during the last twenty years in regard to scientific teaching in our public schools.

OSWALD H. LATTER.

Charterhouse, Godalming, July 2.

June 29, 1904.—SEVENTH PAPER.
(Alternative with Latin Verse.)

COMMON EXAMINATION FOR ENTRANCE TO PUBLIC SCHOOLS.

SCIENCE.—(*One hour.*)

I.—*Physics.*

(1) A weight hangs by two strings each making an angle of 60° with the vertical. Show that the tension of each string is equal to the weight.

(2) A uniform rod 10 feet long and weighing 5 lb. is pivoted 3 feet from one end. A weight of 50 lb. is hung on the end nearer to the pivot. Find what weight must be hung on the opposite end to balance the rod.

(3) Gravity is often measured by the number 32. Explain this. A body is thrown up with a velocity of 48 f. s. In what time will it lose its velocity? In what time will it return to the hand? How high will it go?

(4) A rectangular vessel on a square base is filled with water. Find the relation between the height of the vessel and a side of the base in order that the fluid pressure on one vertical face may equal that on the base.

II.—*Botany.*

(1) Enumerate the floral whorls from outside inwards. Explain what is meant by cohesion and adhesion among floral organs. Make a careful drawing of the section through a flower in which petals and stamens adhere to the calyx tube. Name a flower in which you have observed this structure.

(2) A potato is often spoken of as a root. Is this correct? Give reasons. Name three other cases in which a similar error is made, explaining the real nature of the organ in question.

(3) Draw sections shown in cutting lengthwise through a bean (or acorn) and a grain of barley (or date stone). What difference would be observed during their early growth? Of what great divisions of plants are these characteristic respectively?

(4) What plants would you expect to find in flower in a damp wood on a clay soil in April? Describe one or more of them.

An Early Mercury Pump.

IT may interest some of your readers to know that as early as 1820 an air pump was described depending on the formation of a Torricellian vacuum, and therefore on the same principle as Geissler's and its successors. The paper is by M. Fafchamps—"Description d'une machine pneumatique à l'aide de laquelle on opère le vide sans le secours de la pompe" (*Annales générales des Sciences physiques*, Bruxelles, vol. vi., 1820, pp. 101–2).

A vertical tube standing in a trough is provided with a stop-cock near its upper end. The tube above the stop-cock has a reservoir at the top, and on each side is a stop-cock, one connected with the vessel to be exhausted and the other to a large funnel. The upper end of the reservoir is also provided with a stop-cock. To work the machine the reservoir is first filled with mercury or some other liquid which is introduced through the funnel, the air being expelled through the stop-cock at the top of the reservoir. When filled with liquid the stop-cock of the reservoir is closed, and communication with the funnel is cut off. The stop-cock on the tube is now opened, when a Torricellian vacuum is produced in the reservoir; on opening the cock connected with the receiver air is withdrawn, and so on.

The author remarks that if mercury is used, the vertical tube must be 758 mm. long; if water, the tube must be more than 10 metres, but the length of the tube may be reduced by diminishing the atmospheric pressure on the

surface of the liquid in the trough below. He also remarks that a machine could be devised which would pump up the liquid and open the stop-cocks at the proper times, and thus make the action continuous.

The paper is illustrated.

July 1. HERBERT McLEOD.

HATS AND HAIR.

PUBLIC attention has been recently directed to the head-gear of civilised man, which, it is held, is neither necessary nor advantageous. We have here one of the attempts of well-meaning reformers to regulate on rational principles the dress of man, and so to assist him in his work of self-adaptation to his surroundings and needs. The object is laudable, and in all probability the scientific truth is with the reformers, but it may be well to review the question on somewhat broad lines.

The scalp is unique among the areas of the human body where hair is abundant, for there has been a notable development of hair in both sexes in this region beyond what can have existed in any of the Anthropoidea that can be placed in the human family tree. This is the more remarkable because man's pelage is a degenerating and disappearing character, except in a few areas. We must assume that when primitive man was in the making, natural selection led to the growth of thick hairy covering on his head which conduced to success in the struggle of life by protection against excessive heat and cold, against rain, and against minor injuries. As he advanced from his ancestral arboreal home into the open, and the range of his life extended, such natural adverse influences as these would call forth useful adaptive modifications, such as increased thickness and length of hair. At a later stage his developing intelligence would bring the same character under the influence of sexual or physiological selection, and this would strongly supplement the earlier factor of natural selection. Between these two factors a very stable character of the race has been produced.

There is considerable evidence that in spite of the stability of this character, the vigour of the hair on the head of man, especially in the male sex, is declining. The complexity of the conditions of civilised life renders it impossible to prove that this is due to the cessation of natural selection and the inability of sexual selection to arrest decline, but it is highly probable that this is the case. The more immediate question is this—is a decline in the growth of hair part of a general degeneration of man's ancestral pelage, or is it due to some factor introduced by man himself? It is declared by the reformers that the wearing of head-gear is responsible for the increase of premature baldness. Hitherto the discussion of the question has consisted of little more than individual opinions and *ex-parte* statements, and it is doubtful if evidence can prove or disprove the doctrine now being advanced. Experiment is, from the nature of the case, out of the question, because of the length of time required and the general complexity of the problem. It would seem that the nearest approach to a solution must rest on analogies derived from other characters of man himself and from the lower animals. The study of adaptive modifications (the "modifications" of Lloyd-Morgan and the "ontogenic variations" of Osborn) shows that they thrive when exposed to the natural conditions amongst which they arose, so long as these do not become excessive.

The wearing of coverings for the head affects the hair which is covered in three ways—the natural forces of sunlight, free ventilation, and movement from wind are prevented, the arteries which supply the skin of the scalp and nourish the hair-follicles are compressed, and nutrition thereby diminished, and the head-dress affords a culture-ground for micro-organisms, being also itself impregnated with them. The absence for the time being of the germicidal effect of the sun's rays and of movement of air, and the warmth and moisture of the contained air are just those conditions which would be chosen for the culture of these low vegetable organisms. Very much of the premature baldness of men is due to dandriff (*Seborrhoea sicca capillitii*), a disorder of the sebaceous glands characterised by excessive secretion of sebum and its accumulation in crusts with an admixture of epithelial débris, which leads to destruction of the hair-bulbs, and this disease is essentially microbic in origin. From these various points of view it seems to be indicated that the wearing of coverings for the head slowly diminishes the vigour of the hair. If this theoretical side of the matter cannot be demonstrated, but is only extremely probable, the practical outcome of it is no less beset with difficulties. A change of custom, if desirable at all, is less called for in the case of women than of men, for in the former the head-gear is mostly of light texture and covers a very small portion of the vertex, at any rate in modern times, and a much larger surface is left exposed to sunlight and air than in the case of men. In addition to this fact it is to be remembered that the evidence for decline in the growth of hair is much less in women than in men. Those whom the practical matter chiefly concerns are children of both sexes, young adults, and all male adults, and to these the reformers speak from a sound physiological basis. Whether or not their advice will be taken, or ignored as a counsel of perfection, remains to be seen, and the change advocated is certain to be the occasion of extravagant partisanship.

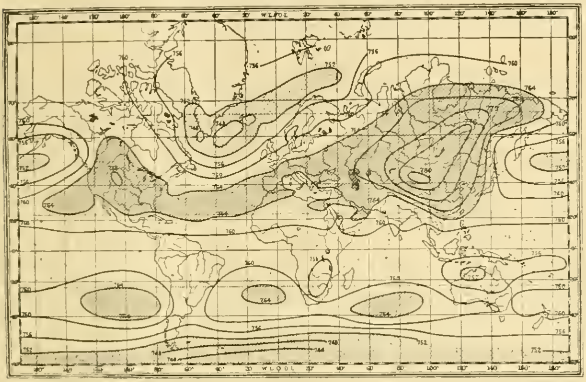
Certain objections to it may be anticipated and removed. First, it will be declared to produce "colds." It is most unfortunate that this name is given to what modern medicine calls "catarrh." The belief that "colds" are produced by exposure to draughts or cold winds is dying hard, and is fortified by the old name so long applied to them, but it is to stultify the great teachings of bacteriology to invoke some casual draught as the cause of disorders of which a nasal catarrh is a type. This danger may be entirely disregarded. It would indeed be for the benefit of the public in more ways than one if they became imbued with the knowledge that pathogenic bacteria of some undetermined species are the efficient cause of all catarrhs. Secondly, it may be feared that inflammatory complaints, such as neuritis or "rheumatism" in the head, would arise from uncovering the head. This is highly improbable considering how large a surface of the head is always uncovered, and that there is no greater protection from hair in the parts uncovered than there is on the vertex. Thirdly, there is undoubtedly some danger, even in temperate climates, from exposure of the head to great sun-heat, and against this danger special precautions are and always would be taken. Fourthly, there is the danger from septic organic matter in towns. This can hardly be reckoned as important, for the area which is necessarily exposed to it is considerable, and proper hygiene of the hair would render it unimportant. Fifthly, injury to the texture of the hair from heat and cold winds is feared, and this again is negligible in view of the fact that the already uncovered parts of the head are better provided with vigorous hair than the covered parts.

Whether the reformers have scientific truth on their side or not, it is possible that the æsthetic aspect of the matter will prove the stronger.

THE MECHANICS OF THE ATMOSPHERE.[1]

THE motion of the atmosphere at any time is admitted to be so complicated that any approach to a workable representation of it must necessarily be by steps. The motion at any time must be regarded as a temporary divergence from the average motion, and the question naturally arises, What is the nature of the average state of motion about which the

FIGURE 1. SURFACE ISOBARS FOR JANUARY. REPRODUCED FROM HANN'S "METEOROLOGIE."

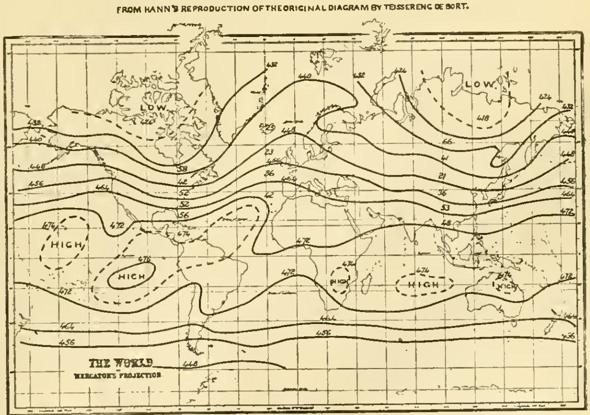


actual state of motion fluctuates? We may approach the solution of this question in either of two ways; we may find out what the motion actually is or we may find what the forces are which, so far as we can tell, cause the motion, and trust to our knowledge of dynamics to compute the average motion from the average forces. As regards the latter method, it may be said that the dynamics of an elastic fluid moving on a rotating spheroid, however interesting, is beset with an extraordinary number of temptations to error, and the more humble ambition of trying to find out what the motion really is, although painfully laborious, has advantages which may be compared with the advantages which walking has as compared with the use of a flying machine.

In the early 'seventies of the last century, Clerk Maxwell set a question in a Cambridge examination to which I owe the inspiration of a number of lectures and examination questions. It was this:—"Show how by observations of the motion of a body the resultant force acting upon it may be determined," and he added the luminous rider (I quote from memory), "A fish weighing 10 lb. swims through the water with a uniform velocity of 10 miles per hour, always in the same direction; find the resultant action of the water on the fish." As soon as one begins to think of answering these questions, and in particular of applying them to the relation between the controlling forces of pressure and the motion of the atmosphere, one realises what pitfalls await the unwary. The most obvious remark in relation to the first question is that the motion at any instant tells us absolutely nothing whatever about the forces acting. Unless observations sufficient to determine the change of motion have been dealt with, nothing about the cause of motion is known. Yet, in spite of this rudimentary fact of dynamics, obvious enough when it is stated, I cannot help wondering how many students of elementary dynamics ever really get rid of the notion that if you find a body moving in a certain direction you must look for a force in that direction too; we are surrounded with examples to the contrary, but the study of dynamics, being mainly deductive, usually passes them by.

In meteorology it is impossible to avoid the consciousness of temptation to the converse error of expecting to find the motion of air in the direction of the recognised forces. The most obvious force is that due to pressure, and who can resist the temptation of thinking that the flow of air from a high-pressure area to a low-pressure area must be the dominant feature of atmospheric motion? Yet the one great inductive statement in connection with meteorology, Buys Ballot's law, warns us that if we trust to the direction of forces to indicate the direction of motion we shall certainly be misled. Motion along isobars, perpendicular to the gradient, is a closer representation of the actual state of things than motion along the gradient, along, that is to say, the direction of resultant forces.

FIGURE 2. ISOBARS AT THE LEVEL OF 4000 METRES FOR JANUARY. FROM HANN'S REPRODUCTION OF THE ORIGINAL DIAGRAM BY TEISSERENC DE BORT.



Pressures in millimetres: velocities in miles per hour, corresponding to the acceleration for different gradients resulting from the Earth's rotation.

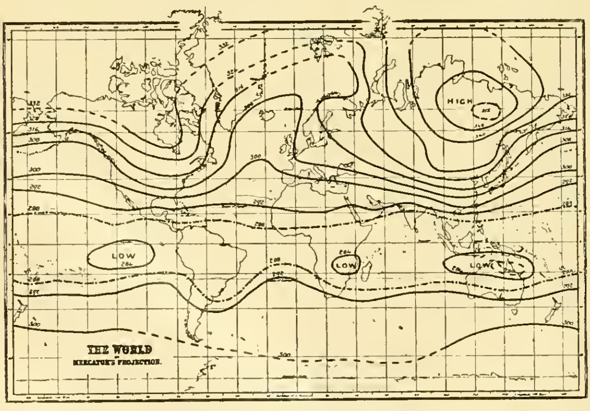
There is no doubt that if we could arrest for a time the motion of the atmosphere, without altering the pressure, and let the air start again from rest, the direction of initial motion would be along the pressure gradients from high to low, but we have to deal with an atmosphere that has been moving for countless ages, and all that existing forces do is to maintain or disturb the average, or steady motion; if in those

[1] Based upon a paper on the "General Circulation of the Atmosphere in Middle and Higher Latitudes," read before the Royal Society on June 2 by Dr. W. N. Shaw, F.R.S.

circumstances we find the motion taking place in the direction of the forces, we find a condition of things which ought not to be expected, and one which requires explanation.

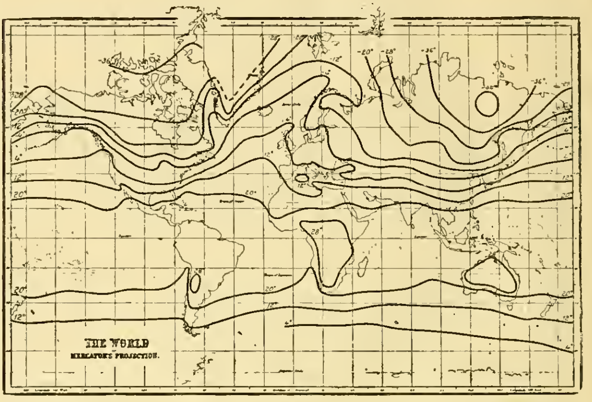
The question arises as to what one ought to expect the steady motion to have become in course of time. To afford some idea of the answer to this question, let me refer to the four diagrams here reproduced. The first gives the average isobars for January at the earth's surface, and discloses no simple representation of steady conditions. There are the well known high-pressure areas about the tropics, and isolated regions of low pressure over the North Atlantic and Pacific; but when we look at Fig. 2, the isobars computed by Teisserenc de Bort for the 4000-metre level, there is an indication of comparatively simple steady motion, namely, a motion round the polar axis from west to east, somewhat deviated, however, to south or north by land or sea areas. Now if we assume that the motion is along the isobars thus represented, so that the lines of the diagram practically represent lines of flow of air, we must remember that the motion on a rotating earth implies a certain normal acceleration of the air to keep it in its path, just as the bob of a conical pendulum requires an acceleration towards its equilibrium position to maintain its motion in a circular path. The effective horizontal acceleration of the air is $2\omega V \sin \lambda$, where ω is the angular velocity of the earth, V the velocity of the wind, and λ the latitude.

FIGURE 3. MEAN PRESSURE DUE TO THE WEIGHT OF THE STRATUM OF THE ATMOSPHERE BELOW 4000 METRES. FOR THE MONTH OF JANUARY. COMPUTED FROM FIGURES 1 AND 2. PRESSURES ARE GIVEN IN MILLIMETRES.



Of the velocity at the 4000-metre level we can only form an idea from the observed motion of clouds, and, so far as we know, the only forces available to give the necessary acceleration are those due to the pressure distribution which Teisserenc de Bort has plotted. By equating the pressure gradient to the product of the density and acceleration we can determine V, and the values thus computed are shown in miles per hour by figures between the isobars on the diagram. They must not be confused with the pressures, which are given in millimetres. The average wind velocities thus computed are not at all unreasonable, and it follows that motion along Teisserenc de Bort's isobars at about 50 miles per hour is not at all an unreasonable representation of the average steady motion of the atmosphere at that level in the month of January. That the directions of motion are appropriate is confirmed by Hildebrandsson's report on cloud motion to the International Meteorological Committee.

FIGURE 4. MEAN TEMPERATURE AT THE EARTH'S SURFACE. FOR THE MONTH OF JANUARY. IN CENTIGRADE DEGREES.



So much for the upper air; the motion is comparatively simple. Then it might be supposed that the complexity of the surface motion is due to extreme complexity of pressure in the lower stratum. The pressure due to the weight of the lower stratum is shown in Fig. 3, which gives the pressure differences between Figs. 1 and 2. There is, strange to say, no more complexity about this distribution than there is about the pressure of the upper layer; in fact, the lines of the two are extraordinarily similar, only the pressure gradients run in opposite directions. Writing "high" for "low," the one diagram would not be an unsatisfactory duplicate of the other, except that the lower stratum has a dislocation of the pole of high pressure from the geographical pole to north-eastern Siberia. Applying the same principle of motion to this diagram as to Fig. 2, it would represent, with suitable velocities calculated in a similar manner, a circulation from east to west in each hemisphere round the pole of cold.

Compare both these diagrams with Fig. 4, representing the surface isothermal lines—the similarity is again conspicuous. The intervals are for every 8° C. of temperature instead of 8 mm. of pressure, and speaking broadly of the temperate latitudes, starting

from a suitable datum temperature or pressure, the lines might be interchanged, a step of one degree of temperature (Fig. 4) corresponding to a step of one millimetre of pressure in the same direction for the upper layer (Fig. 2), and in the opposite direction for the lower layer (Fig. 3).

The complexity of the surface pressure arises, therefore, not from the upper layer alone, nor from the lower layer alone, but from the superposition of the two. We can resolve the surface pressure into two components, one due to the upper stratum above 4000 metres which, if it acted alone, would produce a general circulation from west to east around minima of pressure near the poles; the other, due to the lower stratum, which, if it acted alone, would produce a circulation from east to west. Both circulations would correspond closely with the surface distribution of isotherms. Where the one is predominant, in the lower middle latitudes, we get resultant westerly circulation; where the other is predominant, near the poles of cold, we get an easterly circulation. Between the two we get a region of minimum pressure and a merging of the two circulations which gives rise to the circular storms of the northern and southern temperate zones.

It appears, therefore, that we ought to regard the surface distribution of temperature as giving rise to a distribution of pressure in the lower stratum tending to maintain a circulation of air from east to west round the poles of cold. Extending this idea, a region of cold in the northern hemisphere should tend to maintain a clockwise circulation round its centre in the lower atmosphere, and a region of heat a counter-clockwise circulation.

The reciprocity between the pressure distribution of the upper and lower layers is of course not fortuitous. Hann has shown that the expansion of the lower layer by heat increases the pressure at a given level in the upper regions, without altering the pressure at the surface, by the mere thrusting of part of the air upwards; so that the observed effect of expansion over a large area is to diminish the pressure of the lower stratum and increase, by an equal amount, that of the upper. Referring to the diagrams again, the effect of increased surface temperature upon the isobars of Fig. 3 would be a bulge of the isobars towards the region of low pressure—the equatorial regions; upon the upper isobars there would be a corresponding bulge towards the region of higher pressure, again the equatorial regions. Thus the lines of both diagrams would be affected geographically in an exactly similar way and to the same extent; they would thus preserve their similarity in spite of temperature variations at the surface.

It would be interesting to consider what the effect of the daily solarisation of the earth should be from this point of view. Primarily it should produce no pressure variation at the surface; but inequalities of motion in the upper and lower air would probably alter the relative phase or magnitude of the disturbance of the two components, and hence give rise to daily variations of pressure at the surface, and thus necessarily produce a diurnal variation of the barometer.

Other consequences follow from the treatment of the distribution of pressure due to the weight of the lower layer as producing, or rather maintaining, a circulation in the one direction or the other about the colder or warmer regions, as the case may be, instead of flow from cold regions to hot.

One important result as regards the formation of circular storms in our latitudes may be inferred from this method of analysing the distribution of surface pressure. Friends have frequently suggested to me that our circular storms are like the eddies formed when water flows through a bridge; and to them I have always put the question, What in the atmosphere stands for the bridge? I am now prepared to recognise that the caps of relatively cold air in the north and south polar regions form an adequate representation of the piers of the bridge. In the lower air, where the pressures of the polar caps are dominant, they stop the westerly currents which still flow in lower latitudes, and replace them by currents from the east. Between these two currents is a field where mixing must take place, and circular eddies may be formed.

What happens in the equatorial regions is another story. Buys Ballot's law shows that the equator is subject to a peculiar meteorological condition. If you stand with your back to the wind north of the equator, the low barometer is on your left; south of the equator, it is on your right. There must be a transition region where the law ceases to apply, as, indeed, one would expect if Buys Ballot's law is the practical expression of motion with an acceleration due to the rotation of the earth, and varying as the sine of the latitude.

In the upper air of the equatorial regions there is probably a persistent flow from the east, as shown by observations of clouds and of the Krakatoa dust. In respect of the formation of eddies, this current will act like an intermediate pier of a bridge. Hence, in January, the river in which, upon this analogy, atmospheric eddies may be expected is a stream of air flowing round the earth in middle latitudes, divided by the equatorial belt with its region of doldrums below and easterly current above, and bounded north and south by easterly currents which correspond with the circulation of the lower atmosphere induced by the predominant influence of the polar caps of cold air. Eddies may be looked for between the easterly and westerly currents, and they are sometimes found there.

W. N. SHAW.

NOTES.

THE trustees of the Carnegie Institution met on May 18 and transacted the necessary business to provide for the transfer of all matters to the Carnegie Institution of Washington, a charter for which passed Congress and was approved on April 28. The trustees named in the Act met at once and reorganised under the new charter. The by-laws of the Carnegie Institution were adopted as the by-laws of the new organisation, and the officers of the old organisation were elected. General resolutions adopting all the obligations, &c., of the old institution were passed. Under the new charter no questions can be raised as to the competency of the institution to carry on the operations outlined in the deed of gift of the founder. The executive committee of the Carnegie Institution of Washington met after the reorganisation, and practically completed the making of grants for the year 1904. It will greatly facilitate the work of the executive committee if all those thinking of making applications for grants for 1905 will do so not later than September, as applications for grants for 1905 will then be taken up.

A SLIGHT but decided earthquake, which lasted about a second, was experienced at Derby at 3.22 p.m. on July 3. The vibration was not nearly so pronounced as on the occasion of the seismic disturbance a year ago. A similar shock was felt in the mid-Cheshire district about the same time. In Leftwich, near Northwich, the tremors were very distinct. The shock, which was also felt in Northwich, lasted two seconds, and at Sandbach four seconds. Two shocks

were felt in Sheffield and the surrounding district. The tremor was from west to east. At Matlock Bath there were shocks running from north-east to south-west. The tremor appears to have been felt almost simultaneously throughout Derbyshire, south Yorkshire, Cheshire, and Staffordshire. Writing from Leek, Staffs, Mr. G. H. Martyn says the disturbance occurred there at 3h. 22½m. ± 1m. p.m. "It seemed to be a succession of about a dozen shocks in three seconds. The shocks increased to a maximum at about the third, and then diminished until imperceptible." Dr. Davison found a very slight record of the disturbance upon his seismometer at Birmingham.

THE death is announced of Prof. T. Bredichin, formerly director of the Pulkowa Observatory.

THE Vienna Academy of Sciences has awarded its Baumgarten prize, of the value of about 160*l.*, to Prof. Walter Kaufmann, for his investigations on the theory of electrons.

THE first meeting of the trustees of the Percy Sladen fund for the assistance of scientific research (see p. 182) was held at the Linnean Society last week. The trustees will not meet for the consideration of the first applications before November next, and such applications should be addressed to the clerk to the trustees of the Percy Sladen Memorial Fund, care of the Linnean Society, Burlington House, London, W., by the 1st of that month.

THE Congress of the Royal Institute of Public Health will be held at Folkestone on July 21–26, the Earl of Radnor presiding. In the preventive medicine section, Dr. Nash, medical officer of health, Southend, will open a discussion on a clean milk supply. In the section of bacteriology, Dr. Klein, the president, will give an address on the aim and scope of bacteriological analyses of water and shell-fish with reference to sewage pollution, and the report of a committee appointed to inquire into the methods of bacteriological analysis of water will be presented by Prof. Hewlett. Valuable papers and discussions are promised in the other sections—engineering, child study, and tropical medicine.

AT the second annual general meeting of the fellows of the British Academy, held on June 29, Lord Reay was re-elected president, and the following corresponding fellows were elected, this being the first occasion on which such fellows have been elected:—Count Ugo Balzani, Prof. H. Diels, M. le Comte de Franqueville, Prof. M. J. de Goeje, Prof. I. Goldziher, Prof. T. Gomperz, Prof. J. L. Heiberg, Prof. K. Krumbacher, Prof. F. Leo, M. Paul Meyer, M. Georges Perrot, M. Georges Picot, and Prof. C. H. Salemann. Sir Richard Jebb read a paper on Bacchylides, dealing chiefly with three topics—the illustrations of his mythology supplied by ancient art, the traces of earlier or contemporary literature in his poems, and his relation to Pindar.

A BANQUET was given to Mr. Chamberlain on June 30 by the Royal Institute of Public Health, in recognition of his services to preventive and tropical medicine. In acknowledging the honour, Mr. Chamberlain referred to the progress made in recent years in medicine and surgery. He remarked in the course of his speech that the light which had been thrown on the origin of disease justified the belief that "we are on the eve of great discoveries which will relieve the human race from some of the greatest scourges which have affected it. Now, at any rate, the importance of securing healthy conditions of life is recognised by everybody who cares for the welfare of his fellow-creatures. Preventable disease, at this moment, is, as we all know, a great agent for filling our workhouses, for raising our taxes, for weakening the fibre of the people, for preventing us from competing successfully in that eternal struggle for existence which must go on as long as the world shall last. In peace it is of the utmost importance, in war the same cause destroys more of our soldiers than the bullets or the swords of the enemy, and meanwhile the administration of the Army is lessened in efficiency by the preventable disease to which the agents of the Empire are constantly subject. It is to the efforts of men like Sir Patrick Manson, Major Ross, Prof. Haffkine, and others who have been devoting their time and atention to tropical medicine, to research into the causes of tropical disease, with the remedies for those diseases—it is to that branch of the science that my attention is chiefly directed."

DURING a recent expedition under the auspices of the Geographical Society of Baltimore for the purpose of making scientific researches in the Bahamas, Mr. O. L. Fassig made some interesting experiments with kites at Nassau, one of which was made from a steamer hired for the purpose. The ascents were made in the early part of July, 1903, and the results are published, with diagrams, in the *Monthly Weather Review* for December last. From an average of four ascents and seventy observations, there was a decrease of 1° F. for each 100 feet of elevation up to an altitude of 500 feet; from 500 feet to 1000 feet the decrease was 1° in 143 feet; from 1000 feet to 1500 feet 1° in 167 feet; between 1500 feet and 4000 feet the average decrease was 1° for each 191 feet of elevation. As regards relative humidity, there was a steady increase from the surface (73 per cent.) up to 4000 feet (96 per cent.), with the exception of a small drop near the 3000-feet level; this drop was probably due to an excessive value caused by the kite passing through clouds just below the 2500-feet level on several occasions.

WE have received from Mr. H. Arctowski, a member of the Belgian Antarctic Expedition, a summary of the meteorological results made on board the *Belgica* during its detention in the pack-ice. The paper in question is an excerpt from the *Annuaire météorologique* of the Brussels Observatory for 1904; the volume containing the hourly meteorological observations is now in the press; five memoirs dealing with other special matters have already been published. The *Belgica* entered the "pack" on February 28, 1898, and left it on March 14, 1899; during this period the ship was drifting over an area about the size of the Kara Sea. The author has discussed the daily and monthly means of the observations during a year, as if they were made at one fixed point; the results, therefore, can only be taken as approximately correct. The mean temperature of the year was 14°·7 F., maximum 36°·5 on December 27, minimum −45°·6 on September 8. The diurnal variation was notably different in the several months; grouping the three summer months together (December to February), the amplitude of the variation was 3°·8, while in winter (June to August) it was only 1°·1; in November it amounted to 8°·5. The amount of precipitation is not given; snow fell on 260 days and rain on 20 days. Between March and September auroræ were observed on 61 occasions; the phenomenon was last seen during the night of March 12–13, 1899. Fog or mist was observed on 261 days.

WE have received two important papers dealing with extensions of the theory of Bessel's functions. One is by Prof. C. Cailler, in the *Mémoires* of the Geneva Physical and Natural History Society (xxxiv., 4), and contains an application of the operation designated by M. Schlesinger as Laplace's transformation; the other is a con-

tribution by the Rev. F. H. Jackson, of H.M.S. *Irresistible*, to the Edinburgh *Transactions* (xli., 1), and deals with generalisations of certain expansions in terms of Bessel functions.

IN the *Atti* (xxxvi., 2) of the College of Engineers of Milan, Dr. G. Finzi and Dr. Nicola Soldati describe some interesting experiments on the resistance of bodies moving through air, which should have an important application to the problem of aërial navigation. The chief point of interest consists in the application of the so-called "manometric" method as opposed to the ordinary "dynamometric" method, whereby the present writers have determined the pressure at different points of planes, aërocurves, cylinders and spheres, instead of merely measuring the intensity of the resultant thrusts. For determinations of the variations in the position of the line of action and centre of pressure, such calculations should be of great value, and it is largely in these determinations that the solution of every problem in aërial navigation must lie. A gold medal has been awarded to the authors.

THE March number of the *Mémoires* of the Physical and Natural History Society of Geneva contains a general report of the work of the society for 1903 drawn up by the president, M. Paul van Berchem. The society has completed a new agreement with the municipal authorities, superseding the old agreement of 1855, which will afford the members additional facilities for the use of the town library, in which the publications of the society are deposited. Obituary notices are given of M. Alphonse Pictet, the traveller; of M. Théodor von Heldreich, the botanist; and of M. Théodore de Saussure. Profs. René Blondlot (Nancy) and Walther Spring (Liège) have been elected honorary members, and the *Mémoires* include an important paper by Marc Micheli on the Leguminosæ collected in the Mexican States by Eugène Langlassé.

WE have to acknowledge the receipt of three fasciculi (Nos. 1376–8) of the *Proceedings* of the U.S. National Museum. In the first of these Mr. H. G. Dyar catalogues the Lepidoptera of the Kootenai district of British Columbia, while in the second Messrs. Jordan and Snyder publish notes on fishes collected in Oahu and Laysan Islands, of the Hawaii group, with descriptions of new species.

IN the *Atlantic Monthly* for June, Mr. T. C. Smith records the results of his efforts to reproduce in musical notation the song of the various local phases of the American bird commonly known as the wood-thrush. The score will not enable the musician to reproduce the actual timbre of the song, all that it attempts being to symbolise roughly the tones of the musical scale to which the notes of the bird approximate.

THE Hon. Walter Rothschild has presented to the British (Natural History) Museum a female of the basking shark (*Cetorhinus*, or *Selache*, *maximus*) from Bergen, which has been set up by Messrs. Brazenor Brothers, of Brighton, and measures 26½ feet in length. The new specimen has replaced the male which has for some years been exhibited in the fish gallery, and is now somewhat the worse for wear. The male measures 28 feet, and is mounted with the mouth open, while Mr. Rothschild's specimen is shown with the jaws closed.

THE *Field-Naturalists' Quarterly* for June is a good number, containing interesting articles on British social wasps, protective coloration in plumage, and on the means of recognising our commoner birds. Mr. Aflalo also contributes a paper on south coast museums, which, if a little wide of the scope of the journal, conveys some useful information on their contents. The editor takes occasion to urge that in future the British Association should assign either a day in each of the sections devoted to subjects in which the field-naturalist is interested, or a special section to field natural history.

BIRMINGHAM University has issued an exhaustive report, by Mr. W. E. Collinge, on the "big-bud" disease which of late years has played such havoc among black-currant bushes in this country. The disease is produced by the black-currant gall-mite (*Eriophyes ribis*), the larvæ of which display unrivalled powers of spreading themselves over plantations. Although some success has attended the use of soap and sulphur spray, the author is of opinion that growers must rely largely on the aid of natural enemies of the pest, or on root and branch extermination of the affected bushes.

THE *Zoologist* for June contains an interesting paper by Mr. J. H. Gurney on birds and bird-migration in Norfolk and the east coast generally in 1903. As regards migration, it is pointed out that the prevalence of east winds is an important factor in producing an influx of visitors to this country, and also that while birds may leave Norway with a favourable wind *en route* for England, they are often driven from their course by encountering contrary breezes as they cross the North Sea. A notable incursion of waxwings during the year affords occasion for the remark that these birds do not visit England on account of excessive cold, but come under the category of late occasional migrants. Other rarities include a young sea-eagle, a flock of Nyroca ducks, half a dozen spoonbills, an avocet, and a blue water-hen. Spoonbills have made their appearance on the east coast continuously since 1897, and hopes are now entertained that they may once more breed in this country. To the same journal Mr. G. Renshaw contributes notes on the Amsterdam Zoological Gardens, in the course of which he repeats his mis-statement that the mounted quagga in the museum came from Knowsley.

IN the report for 1903, the trustees of the South African Museum take occasion to direct attention to the apathy displayed by the wealthy residents of South Africa to the institution under their charge, thereby presenting a regrettable contrast to their fellow millionaires in the United States. During the last twenty years all that the museum has received in the way of bequest and donation is the paltry sum of 295*l*., of which 100*l*. was given by an Indian gentleman. So far as its limited means permit, the museum appears to be making steady progress.—During the past year, according to the report, the attention of the staff of the Horniman Museum was largely directed to the development of the aquaria and vivaria which form such an attractive feature of that institution. A large number of British marine, land, and fresh-water animals have been from time to time on show during the year in the tanks and cases. Dr. Haddon's series of lectures appears to have been fairly well attended.—In the report of the Marlborough College Natural History Society, the secretary has to deplore the disastrous effect of the wet summer of 1903 on collecting and field-work generally, which has made itself felt in a decline of membership. The one compensation was the abundance of land molluscs, which was taken advantage of to compile a list of the local fauna. In other respects the society continues to flourish.

IN NATURE of February 11 (p. 349) we gave some particulars of the great rock-slide which occurred last year at Frank, in Alberta Territory, Canada. A full and interest-

ing report on the subject, by Messrs. R. G. McConnell and R. W. Brock, has since been issued by the Geological Survey of Canada (part viii., Ann. Rep. for 1903). The conclusions arrived at fully confirm the explanations previously given by Mr. Brewer, but the authors add that recent earthquake tremors no doubt hastened the time of the final disruption. They regard the present state of Turtle Mountain as dangerous, and recommend the removal of the town of Frank to a site higher up the valley of the Old Man River. The report is illustrated by map, sections, and numerous pictorial views.

The Geological Survey of India has revived the publication of its *Records*, a serial which was established in 1868, and amalgamated with the *Memoirs* in 1897. In justification of this step, the director, Mr. T. H. Holland, points out that during the course of the survey work many observations are made from time to time that it would be advisable to publish as promptly as possible, on account of their bearing on current scientific problems or of their economic value. The present number (vol. xxxi., part i.) contains accounts of coal-deposits, copper ore, sapphirine-bearing rock, together with miscellaneous notes on tin-ore, gem sands, &c., and selections from assays made in the laboratory relating to coal and manganese-ores. Mr. Holland expresses the hope that contributions will be made by private workers, to whom the *Records* will be open for original observations on geological subjects.

In the April *Bulletin* of the Johns Hopkins Hospital (xv., No. 157), Dr. George Dock discusses vaccine lymph and vaccination especially as regards American practice. Dr. Watts Lee publishes studies of the sinus frontalis of man and of certain mammals, carried out both by dissections and by means of lead casts, and Dr. Hastings describes a new blood stain possessing advantages over the Romanowsky and Leishmann stains, which should prove very useful, as it is permanent in the preparations, and the solution keeps well.

In Nature of March 17 (vol. lxix. p. 467) a review was given of the anti-malarial operations at Mian-Mir. A second report on the subject has now been published, and gives additional details (*Sc. Mem. of the Gov. of India*, No. 9, by Lieut. S. R. Christophers, I.M.S.). The conclusions are in accordance with those expressed by Captain James, I.M.S., in the first report. It is found that the destruction of the anopheles mosquito within an area by attacking their breeding places is extremely difficult, the mere obliteration of local breeding places being useless. Thus at Mian-Mir, although large numbers of pools were filled up and drained, and almost complete absence of breeding was ensured to a distance of half a mile, adult anopheles still appeared in large and increasing numbers, apparently due to immigration from without. Although a distinct effect was produced on the incidence of malaria among the troops and on the endemic index of the native bazaars, it was only evident at the beginning of the fever season, and could not be maintained. The value of quinine administration was found to depend on the efficiency of the supervision exercised; when quinine was regularly taken the admission rate for fever was much reduced. The conclusion is formed that although some effect on malaria was produced by anti-mosquito measures, these are not those best adapted at Mian-Mir to the eventual reduction of malaria.

The third issue of *The Central*—the journal of the Central Technical College Old Students' Association—is an excellent number. Prof. Armstrong, F.R.S., contributes the first of a series of short articles on the mechanism of combustion. Among other articles we notice two which are illustrated—one on popular motor cars, by Mr. M. O'Gorman, and the other by Mr. R. W. Sindall, on the manufacture of wood-pulp.

A second edition, revised and enlarged, of the "Student's Handbook of British Mosses," by Mr. H. N. Dixon, the first edition of which was reviewed at length in our issue of September 10, 1896 (vol. liv. p. 434), with illustrations and keys to the genera and species by Mr. H. G. Jameson, has been published by Mr. V. T. Sumfield, Station Street, Eastbourne. Since the publication of the first edition of the book, some thirty species or subspecies of British mosses have been detected, together with a corresponding number of varieties. These additions have been interpolated in the second edition, and notes also have been provided where recent knowledge necessitated their inclusion. Some slight alterations, too, have been made in the general arrangement of the book.

OUR ASTRONOMICAL COLUMN.

The Number of the Stars.—In No. 114 of *Popular Astronomy*, Mr. Gavin J. Burns makes some calculations and deductions as to the number of stars in the entire sky from the various star catalogues and photometric durchmusterungs which have been published. On the assumption that, on the whole, the stars are evenly distributed, he deduces from the plates taken for the Greenwich zone of the Astrographic Chart that there are 38 stars brighter than the second magnitude, 13,421 brighter than the seventh, and 8,325,000 brighter than the fifteenth. The ratio of the total number of stars brighter than any one magnitude to the number brighter than the next magnitude fainter is fairly constant at about 3·4 until the tenth magnitude is reached, but beyond that there is a sudden drop to 1·9, which ratio continues down to magnitude 15. From this discussion there is strong presumptive evidence that the stars thin out as their distance from our system increases.

Radial Velocities of the Pleiades.—From an investigation of a series of plates taken with the Bruce spectrograph, using only *one* prism, Mr. W. S. Adams, of the Yerkes Observatory, has determined the radial velocities of the Pleiades stars as follows:—

Name.	Bessel's number.	Mag.	Mean vel. in km.
Electra ..	17 Tauri ...	3·8 ...	+15
Taygeta ...	19 ,, ...	4·4 ...	+ 3
Merope ...	23 ,, ...	4·2 ...	+ 6
Alcyone ...	25 ,, ..	3·0 ...	+15
Atlas ...	27 ,, ...	3·8 ...	+13

Measurements of seven spectrograms of Maia (20 Tauri) indicate that this star has a variable velocity ranging from −7·4 km. (October 30, 1903) to +20·9 km. (December 25, 1903). The lines in the spectrum are well defined, so that although the range of variability is not very large, it is almost certainly real.

The spectra of Maia and Taygeta are at variance with what we should expect to find for stars associated with a nebula, and they engender a suspicion that these stars may not be physically connected with the surrounding nebula (*Astrophysical Journal*, No. 5, vol. xix.).

An Expedition for Solar Research.—With the aid of a grant of 10,000 dollars from the Carnegie Institution, the Yerkes Observatory has sent an expedition to Mount Wilson (altitude 5886 feet), near Pasadena, California, for the purpose of making special investigations of the sun.

The Snow horizontal telescope is to be the principal instrument erected. One of the concave mirrors of the coelostat reflector, having a focal length of 145 feet, will give a solar image 16 inches in diameter, and will be used for special spectroscopic studies of sun-spots and other solar phenomena. A spectroheliograph of 7 inches aperture and 30 feet focal length is also to be used in connection with this mirror. A stellar spectrograph provided

with a large concave grating is to be used to obtain, if possible, spectra of the brighter stars. The expedition is under the immediate direction of Prof. Hale.

THE ORBIT OF COMET 1889 IV.—The following elements for comet 1889 IV. have been calculated by Dr. Guido Horn, of Trieste, and are published in No. 5, vol. xxxiii., of the *Memorie della Societa degli Spettroscopisti Italiani*:—

$$\begin{aligned} T &= 1889 \text{ July } 19{\cdot}32298 \text{ (M.T. Berlin)} \\ \varpi &= 345^\circ\ 52'\ 42''{\cdot}83 \\ \Omega &= 286^\circ\ 9'\ 18''{\cdot}31 \\ i &= 65^\circ\ 59'\ 11''{\cdot}17 \\ \log q &= 0{\cdot}0169197 \\ \log e &= 9{\cdot}9990087 \\ \log a &= 2{\cdot}6590039 \\ \text{Period} &= 9738{\cdot}81 \text{ years.} \end{aligned}$$

A table showing the similarity of the orbit of this comet to those of six others which have appeared since 1684 is also given.

NEW LISTS OF VARIABLE STARS.—*Circular* No. 79 of the Harvard College Observatory contains a list of 19 new variable stars situated in the constellations Orion and Carina, and a list of 57 new variables in the region of the small Magellanic Cloud. A careful examination of 1167 star images, contained in a region 30′ square, on two plates of the Trifid nebula revealed no variables.

Circular No. 80 gives the positions and spectral characters of six new variables discovered by Mrs. Fleming on the Draper memorial photographs.

Circular No. 81 is devoted to some notes on eight variable stars of long periods prepared by Miss Cannon from her observations with the 6-inch telescope. The notes contain short comments upon the individual observations and on the agreement of the observed magnitudes on different dates with the various published elements for each star.

THE EDUCATION OF THE AMERICAN ENGINEER.

THE growing success of American and German manufacturers in the international competition for the world's markets has in recent years commanded alike the earnest attention of our industrial leaders and of our educational authorities. As numerous articles in these columns have testified, many serious attempts have been made during the past few years by expert observers from this country to try to discover the precise connection between foreign industrial success and the educational systems of the countries the competition of which has been brought home to us most decidedly; and the greatest attention has perhaps been given to the manner in which foreign engineers are prepared in schools and colleges for their life's work. It is little more than a year ago that Prof. W. E. Dalby laid before the Institution of Naval Architects and the Institution of Mechanical Engineers the results of his commission from Mr. Yarrow to report on the training of engineers in other countries, and as recently as May 5 the report of the Mosely Educational Commission, which dealt at some length with the same subject, was reviewed in NATURE. The most recent contribution to this important subject is a paper by Dr. Mullineux Walmsley read before the Institution of Electrical Engineers, and published in the *Journal* of that society for May. Dr. Walmsley was given leave of absence by the governing body of the Northampton Institute, of which he is principal, and was instructed to investigate the methods of higher engineering education in the United States and Canada, and more particularly the effect, so far as it could be ascertained, of the education on the engineering industries, the views of the great manufacturers and employers on the value of the products turned out by the schools, and the attitude generally taken up by them towards these schools. The paper embodying the chief conclusions at which Dr. Walmsley arrived and the more important of his observations runs to fifty pages, and a few typical examples only can be given in the space available.

The paper is divided into six sections, the first five of which are concerned with higher mechanical and electrical engineering education to the practical exclusion of other branches of engineering instruction. It was originally intended to include a chapter on the training of bench hands, fitters and erectors, but eventually Dr. Walmsley contented himself with the statement that in many respects "our arrangements here for the training of bench hands, &c., are better than the corresponding facilities provided in the United States and Canada."

The engineering schools and their resources are first described. The number and extent of the buildings devoted to higher engineering education exceeds, says the paper, anything that we can show in this country, but more often than otherwise Dr. Walmsley found that the supply of buildings was proving inadequate. There is evidence throughout these American schools of lavish expenditure on equipment on a scale to which we are, as yet, quite unaccustomed. The laboratories and workshops are packed full of apparatus and machinery for the use of students. The author states, "it is difficult within the limits of a paper not dealing exclusively with equipment to convey an adequate idea of its complexity or extent to those who have not visited the actual laboratories." The special needs of teachers and students engaged in research work receive particular attention by those who are responsible for the equipment of engineering workshops and laboratories, and the apparatus and fittings available include delicate instruments unlikely to be required by the ordinary student, but available for special investigations. It is interesting in this connection to quote an expression of opinion by Prof. Armstrong in the discussion on the paper:—"There may be a good deal of provision made for research, but there is not much evidence of research work being done. What the colleges are suffering from very largely is great over-provision of appliances and under-provision of teachers and well-prepared students."

Dr. Walmsley's remarks on the staffs of American engineering institutions agree with expressions of opinion to be found in the reports of Profs. Ayrton, Maclean, and Ripper in the volume dealing with the Mosely Educational Commission. It may be said to be generally admitted in America that professors of engineering must be practical men possessing a modern working acquaintance with engineering processes on a commercial scale rather than men possessed of high academic qualifications. It is recognised by Transatlantic authorities, too, that it is all to the advantage of the students if the professor is also actively engaged in engineering practice, either as an advising expert or in some other capacity.

Financial considerations are given great prominence in the paper, and much the same ground is covered as that traversed by an article in NATURE of May 14, 1903, on "The University and the Modern State," though Dr. Walmsley, in addition, makes an interesting attempt to separate the expenditure on engineering from that on higher education as a whole. Many of the conclusions arrived at by Sir Norman Lockyer in his Southport address to the British Association are quoted and substantiated by the author's own observations.

A comparison is instituted between the mental stock-in-trade with which American and English young men respectively start their engineering training, and though Dr. Walmsley does not claim that the school training provided in the United States is perfect, he has little doubt of the greater suitability of the American training for boys intending to become engineers: "both because of the later age of entrance, and also because their general education, as a rule, has been carried to a higher point, it follows that the candidate for entrance into the technical courses in America is better equipped than those in this country to take advantage of the training of the professional school." Here, again, we find Prof. Armstrong dissenting; he is inclined to doubt altogether whether the average product which enters the colleges in America is in the least degree superior to the average product coming up to our colleges.

Under the heading "The Work of the Schools," much valuable material as to the characteristics of the engineering courses in the colleges of the United States is brought together. The rule is that in the first two years of the course—which generally lasts four years—a fair amount of time is given to mathematics, English, modern languages and experimental science, and it is chiefly in the workshop and drawing office that the specialisation towards engineering is apparent during these two years. Specialisation

begins to show itself prominently early in the third year, and mechanical technology and electrotechnics are more or less taken up in the mechanical and electrical engineering courses. In the fourth year a crowd of engineering subjects is frequently introduced. An important part of the work of the fourth year is the preparation of a graduation thesis. The original intention, we find, of including such work in the time-table was undoubtedly to stimulate each student to produce, before he left the institution, a piece of original work which should be of some value in the development of science or of industry. In actual practice, however, the amount of original work produced is not very great, and it can be said fairly that only the best students do work which may be correctly dignified by the name of research. In most of the colleges post-graduate courses are organised, and in these the best work of the college is done.

But in no respect are American conditions more different from those at home than in the attitude of the employers of labour towards higher education. Just as the engineering experts on the Mosely Commission were unanimous in praising the interest shown by American manufacturers in the work of the colleges, so Dr. Walmsley testifies to the same fact. "Without exception the officials interviewed asserted that, far from having any difficulty in placing the graduates turned out year by year from the engineering courses, for the last few years the graduate class has had every one of its individual members engaged for remunerative work before the completion of the course at college." Later it is stated, "many of the large employers have made it a *sine quâ non* for entrance to any position which may lead eventually to a place on the scientific staff, that the candidate should have passed satisfactorily through the full four years' course at an approved technical institution." More than this, no premium is demanded, and living wages are given from the beginning, and these are raised as soon as the young beginner shows himself to be worth more.

Dr. Walmsley concludes his valuable paper with a summary of the respects in which this country is behind the United States so far as the education of its engineers is concerned. He enumerates the following deficiencies:— First, the comparative lack of support and encouragement of the work of the colleges by our leading manufacturers; secondly, that even were our employers ready to adopt the American plan of securing the services of students from the engineering schools, our present schools are neither equipped nor staffed to produce in sufficiently large numbers the trained men who would be wanted; and thirdly, that parents and guardians in this country have not yet been educated to understand how essential, in view of recent developments, a college training is to the success in the future of a candidate for the engineering profession.

As Mr. Buckmaster remarked during the course of the resumed discussion on Dr. Walmsley's paper, it "will be for a long time to come a sort of mine into which each of us will dig." This report together with the others to which reference has been made are more than sufficient to show educational authorities the direction in which our systems of instruction can be improved, and it is earnestly to be hoped that these and similar warnings will not have been uttered in vain.

A. T. S.

ARCHÆOLOGICAL INVESTIGATIONS IN RUSSIAN TURKESTAN.

DR. D. C. GILMAN, president of the Carnegie Institution of Washington, has received a letter in which Prof. R. Pumpelly describes some interesting results of his investigations upon ancient sites, at Anau, near Aschabad, in Russian Turkestan. The following extract from this communication will be welcomed by all who are interested in prehistoric and archæological researches:—

We have explored more than 136 feet of successive culture strata, containing at least four almost uninterrupted culture stages, extending apparently for thousands of years through the Neolithic and Bronze into the beginning of the Iron stage, and we have correlated the stages of culture with important events in the physiographic history and with the introduction of irrigation.

The streams that rise in the high mountains of northern Persia emerge on to the Turkoman plains forming fans, or subaërial deltas, covering many square miles, and each making an oasis. The water is all used in irrigating these fertile spots. Beyond them is the desert. Anau, where we have excavated, is on one of these fans.

Here at Anau, about seven miles east of Aschabad, there are two great tumuli, and the ruins of a city—Anau—surrounded by moat and wall, and occupied until within the last century. The two tumuli, nearly half a mile apart, are nearly equidistant from the city at a distance of less than a mile. We have explored both of these tumuli, and I have done some work in the city.

The northern and older tumulus rises 40 feet *above the plain*; the southern and younger tumulus rises 52 feet *above the plain*. Both of these start with their lowest culture strata on slight elevations in the same original plain-surface —more than 20 feet below the present surface of the surrounding plain. That is to say, the plain has grown up more than 20 feet since the settlements began. I will show, further on, the different phases of this growth.

In the older tumulus, we find a culture occupying the lower 45 feet, and distinguished by the technique and decoration of its wholly hand-made and interesting pottery. This is succeeded in the upper 15 feet by a more advanced culture in which some remnants of bronze implements and lead beads (all wholly altered to salts of the metals) show a beginning acquaintance with bronze, while the still hand-made pottery has changed and become more developed. Throughout this tumulus we have found nothing recognisable as a weapon of offence in either stone or metal, though flint knives abound.

The southern, younger tumulus, starts with a developed wheel-made pottery, unpainted, and of a technique wholly different from that of the older tumulus—though some hand-made pottery occurs not wholly unlike some of the younger products of the older tumulus.

From its base under the plain to its summit this tumulus has 74 feet of culture strata. There are evident here at least two successive cultures. Of these, that of the lower 62 feet is wholly in the bronze stage (but with survival of flint implements), while the upper 14 feet are marked by decided changes and by the introduction of iron, of which the wholly oxidised remnants of some implements were found.

We have thus at least four distinct cultures occupying 136 feet, with a break in the column between the end of the old and the beginning of the new tumulus. We do not know how great this gap may be.

Through all the cultures except the last—that of the iron stage—there ran a remarkable and characteristic burial custom. The children—at least certain children—and seemingly only children, were buried in the houses, under the floor, on a layer of fire-hardened earth.

In addition to the work on the two tumuli, I have sunk four shafts to the culture strata (30 to 40 feet thick) of the city of Anau, to try to determine its age relative to that of the youngest culture of the tumuli, and to get facts for use in deciding as to when irrigation was introduced. The results prove that Anau was wholly in the iron stage, while its wheel-made pottery is wholly different from any in the tumuli; but, in addition to this, fine-glazed faience was found plentifully in the upper three-quarters of all three shafts. These were not found at all in the tumuli, excepting in the case of two or three isolated and very doubtful pieces.

The history of the whole series of culture strata is sharply characterised by the following four periods in the history of the plain or subaërial delta:—

(1) The north tumulus when founded stood on a hill at least 7 feet, and probably more, above the plain surface, its culture spreading down the slopes. The plain was aggrading, and continued to grow until it had buried the base of the tumulus to a depth of 2 feet. By that time, or soon after, the north tumulus was abandoned, and the south tumulus culture founded, on an elevation about 2 feet above the plain. The plain continued to grow until it had buried the base of the south tumulus to a depth of 14 feet.

(2) Then followed a change of conditions. The plain was cut down at least 19 feet.

(3) This was followed by another change which caused the refilling of the cutting to the amount of 8 feet, 7 feet of this last growth having occurred after the deposition in

its sediments of the thoroughly characteristic pottery of the youngest (the iron culture) of the south tumulus.

(4) After this, and apparently contemporaneous with the founding of Anau, irrigation began through which the plain was raised 15 feet, bringing it to its present condition, in which the north tumulus stands embedded to a depth of 27 feet, the south tumulus to the depth of 22 feet, and Anau to 15 feet.

EFFECT OF SOUND ON WATER JETS.[1]

THE structure of water jets was first investigated by M. Savart, who in 1833 published a series of beautiful papers in the *Annales de Chimie et de Physique*. Since then it has received the attention of many experimenters, notably M. Plateau and Prof. Magnus, while of later years our knowledge of the subject has been much added to by the observations and mathematical researches of Lord Rayleigh. The older experimenters had to content themselves with observing the jet through a revolving disc with radial slots, but by means of an electric spark and rapid plates we can now secure photographs of the jet at any desired instant. The eye shows us that a jet of water consists of two parts, (1) a clear column, and (2) a troubled portion. The spark reveals to us that the troubled portion, though apparently continuous, is really a succession of drops, which move too rapidly for the eye to perceive them as such while under continuous illumination.

FIG. 1.—Some Instantaneous Photographs of Water Jets.

Towards the lower part of the clear column of water the jet presents alternate swellings and contractions, and at the very extremity a drop is cast off, leaving behind a connecting ligament, which separates and forms a smaller drop (Fig. 1). If the jet is falling freely, and subject only to accidental tremors and disturbances, the formation of drops is by no means regular, and the sizes and shapes of the drops vary much. If a vibrating tuning fork be held in contact with the stand, and if the pressure of water and the diameter of the orifice be suitable, the jet will appear like a vibrating string, a succession of nodes and loops being formed. The effect of the tuning fork is to render the separation of the drops regular, a drop being cast off with each vibration of the fork. If the jet be falling vertically, as the drop leaves the end of the clear column it is extended in a horizontal direction, but as it falls it oscillates about the spherical form, being alternately elongated and compressed under the action of the surface tension of the liquid (Fig. 2).

Prof. Magnus explained that the wavy appearance of the jet under the action of the tuning fork was due to all the drops which arrive at any given point of space being in the same phase; at the middle of a swelling they are most elongated horizontally, and midway between the broadest portions of two consecutive swellings they are most elongated vertically.

These remarks apply to a jet of water about 2 mm. in diameter. If the diameter of the jet be much less than 1 mm., swellings are not produced in it. The effect of a tuning fork is to render the drops practically equidistant and uniform in size (Fig. 3). If a fine jet be projected upwards (Fig. 4) it will be seen to consist of irregular drops, while the effect of a tuning fork upon it is often to cause it to break up into several distinct streams (Fig. 5).

[1] "The Structure of Water Jets, and the Effect of Sound thereon." By Philip E. Belas, Royal College of Science, Dublin. With photographs. Abstract of paper read before the Royal Dublin Society on March 15.

THE POISON OF THE BANDED KRAIT.[1]

THERE is an unbounded field in India for the study of the venoms of the many species of poisonous snakes met with in that country, and the Government of India has been well advised to devote to this subject certain of its scientific memoirs now being issued from time to time. Captain Lamb, I.M.S., the author of the one under review, has already done good work in this branch of research.

The venoms of various snakes, though all composed of the same class of chemical substances (coagulable proteids and proteoses) in varying proportion, differ markedly in their physiological actions, and it can be shown not only physiologically, but also by certain test-tube reactions, that the proteids and proteoses are different in the different venoms.

Thus the blood serum of an animal that has been injected with cobra venom causes a precipitate when mixed with an aqueous solution of cobra venom, but has no such action when mixed with a solution of the venom of the Australian tiger snake. As regards the venom of the banded krait (*Bungarus fasciatus*), with which this memoir deals, Captain Lamb's researches show that cases of poisoning may be divided into three classes:—(1) those in which after a large dose rapid death follows from the occurrence of extensive blood coagulation in the blood vessels; (2) those which are fatal after two or three days, and present acute

[1] Scientific Memoirs by Officers of the Medical and Sanitary Departments of the Government of India. No. 7, 1904. "Some Observations on the Poison of the Banded Krait (*Bungarus fasciatus*)." By Captain George Lamb, M.D., I.M.S. (Calcutta: Government Printing Office, 1904

nervous symptoms; and (3) those which run a chronic course and end fatally between the sixth and twelfth days after poisoning. In these, histological examination shows a well marked primary degeneration of the cells of the central nervous system, and to this the fatal issue is due.

The venom of the krait was found to be much less toxic than that of the cobra or of the daboia, and, unlike the former, has only a slightly destructive action on the red blood corpuscles. It, however, markedly increases blood coagulability, and may cause extensive intravascular clotting. Cobra and tiger snake anti-sera possess no neutralising action for the krait venom. The use of anti-sera, the only efficient antidotes for snake bites, must, therefore, unfortunately be limited, for it is necessary to have an anti-serum for the venom of every species. R. T. HEWLETT.

CURRENTS AROUND THE COASTS OF NEWFOUNDLAND.[1]

IN the course of the investigations described by Dr. Bell Dawson, a number of points were met with which are of general interest, as they probably characterise the currents on the margin of any large or oceanic area under similar conditions.

The currents in the above regions were examined last season from May to September, under the personal supervision of Dr. Dawson, the engineer in charge of the Tidal and Current Survey. Special attention was given to the question of indraught into the larger bays on the south coast, and to the behaviour of the Polar current which follows the eastern coast. For this work, the D. G. S. *Gulnare* was equipped with appliances for deep sea anchorage, and apparatus of a modern type, in some ways specially devised for the purpose. At anchorages carefully chosen, which were made in all depths up to 100 fathoms, the speed of the currents was measured, and the direction noted every half hour, day and night. The observations also included the under-current, the density and temperature of the water, the mileage and direction of the wind, and a continuous record of the tide on a self-registering gauge placed in a harbour in the region, for comparison with the set of the current.

The behaviour of these currents is very varied, and they were found to be so weak as to be readily influenced by the wind; but by a systematic reduction of the results, Dr. Dawson has prepared a report which describes the currents as concisely as possible, while avoiding technicalities. The report is divided into two parts; the first deals with the currents met with on the steamship route, which follows the south coast for 180 miles, and the question of indraught into the larger bays; and the second part describes the character of the Polar current on the east coast, and its possible change of direction when disturbed. The report is illustrated by nine diagrams and maps, which represent the results graphically. From this report, the following descriptions and explanations are culled, which are of general interest from a hydrographic point of view. References to the local geography are omitted as far as possible, as they might be inconvenient to follow without the map which accompanies the report.

Nature of the Currents.—The currents were almost invariably less than one knot. As a rule, they veered widely and were irregular in direction; and with so low a speed they were readily influenced by the wind. There were three elements to distinguish:—(1) Any general tendency to set in one direction more than in others. (2) Any tidal influence, which might show itself either as a marked change in the direction of the set, or as a period in which a variation in velocity would recur. (3) The influence of the wind in disturbing the usual behaviour of the current. From the observation, the effect of any storms which occur during the summer season seldom extends to a greater depth than 5 or 10 fathoms; and it was therefore found that the behaviour of the under-current at 15 to 30 fathoms afforded a most valuable indication of the normal character of the current. In these currents, the tidal element is almost invariably present in some form, more or less distinct; and this is almost always combined with a tendency to make on the whole in some one direction. It is not therefore possible to maintain an arbitrary distinction between "constant currents" and "tidal streams"; but the only natural distinction is to use the term *current* for all horizontal movements of the water, and *tide* for the vertical movement from high to low water.

The following features in these currents will be interesting for comparison with the behaviour of currents elsewhere, on the open coast of the ocean:—(1) When more than five miles from shore, there are no currents at any time throughout the season which exceed one knot in any direction. The only exception to this is the Polar current, in which a maximum speed of 1·15 knots was observed. (2) On the south coast, when within four or five miles of the shore, the current is chiefly governed by the tide, and sets in the two opposite directions alternately; but the farther out the point of observation, the greater the tendency for the direction of the current to veer completely around the compass. (3) The Polar current sets very constantly to the south-west, for a width of thirty or forty miles off the eastern coast. During times of disturbance, it may set south-eastward, or even be reversed, on the surface. When such disturbance occurs, it is usually for part of a day immediately before a gale comes on.

In the Polar current the influence of the tide was distinctly marked by a fluctuation in velocity, the current being 24 per cent. stronger during flood tide on the average. The under-current had the same general direction as the surface current. It set constantly to the south-westward, even at times when the current on the surface was most disturbed by the wind, judging from numerous observations at 40 fathoms, or about one-half the total depth of the water. The fluctuation in velocity with the tide was even more marked in the under-current than on the surface. During the flood tide, the strength from 15 to 40 fathoms was unusually constant, and at 40 fathoms it was always as strong and often stronger than on the surface. During the ebb tide it slacked below, as it did on the surface, and was usually weaker at the greater depths. When slackest, at about half-ebb, it fell below one-fourth of its greatest strength during flood tide, but even then the movement was distinctly felt to a depth of 60 and 75 fathoms.

Off the south shore, at an anchorage at an offing of seventeen miles, the behaviour of the current was very variable. During a period of nine days in June, when 158 hours of continuous observations were secured, a variety of weather conditions obtained, although the wind did not ever exceed twenty-one miles an hour. To understand the nature of the current, careful comparisons with the tides and winds are undoubtedly required; but the continuity of observations, taken every half hour day and night, affords a good basis for the comparison, and with an anemometer on board, the wind observations are much better obtained than by comparison with an observatory on shore.

The most evident change in the behaviour of the current is that sometimes the direction veers completely round the compass, and at other times it veers backwards and forwards between limiting directions. This change is evidently due to the variation in the amount of tidal influence with the springs and neaps. The veer completely around the compass occurs at neap tides, this being well marked at the moon's quarters on two different occasions. The veer is then continuously to the right, and the period in which a complete revolution occurs is just about sixteen hours. This period is quite definite, as deduced from six complete revolutions which were observed. It appears to result from a combination of the tidal period with a general movement of the water to the westward. This appears to be the only possible explanation, in accordance with the principles of rotary movement. This sixteen-hour period has been met with at other stations during the season, as well as in other regions in former years. At other times in the month, when the tidal influence is stronger, the current veers to the right and left through a range which varies from eight points to half a circumference. The complete period in which it veers and backs is from ten to fourteen hours. It is not impossible that this veer would be found to correspond with the tidal period if an average were taken which would be sufficiently long to eliminate other disturbing causes. On the other hand, at

[1] "The Currents on the South-eastern Coasts of Newfoundland. From Investigations of the Tidal and Current Survey in the Season of 1903." By Dr. W. Bell Dawson.

the neap tides, when the tidal element has the least influence, the sixteen-hour period throws the direction of the current entirely out of correspondence with the time of the tide.

Wind Influence.—It would be quite erroneous to suppose that the wind always causes a drift in its own direction. On the contrary, the set is primarily due to the nature of the current, and if it has any definite direction of its own, owing to the tide or other causes, it takes a strong wind a considerable time to overcome this, even with currents such as these, which do not exceed one knot.

A set of the current towards the point from which a wind is about to come is in accord with the universal testimony of the fishermen throughout these regions. Of all the signs of bad weather, it is the one which they appear to find the most trustworthy. In the summer, bad weather usually comes from the south-east and "blows itself out" from that direction; but later on, in the autumn, the wind chops round to the north-west before the storm is over. Along the south shore, it is only during ebb tide that there is a weak set to the south-east. Any strong set to the south-east or south is a sign of bad weather. The fishermen regard this as an unfailing indication, and at once run for shelter. The main feature is the fact of the current setting "into the weather," as they express it, and it is difficult to give a satisfactory explanation for this. The actual direction of the current is necessarily modified by local conditions and guided by the trend of the shore, but the greater scope and freedom the current has, the more directly it appears to set towards the coming wind. And further, it will set in either direction in accord with the expected wind. If this behaviour is due to difference of barometer, it is not easy to understand why the water should be the first to feel a change, before the wind itself begins to blow.

Density and Temperature of the Water.—Extended observations of density and temperature were taken during the season. This was done in the hope of tracing the movement of the water, as this method had proved so serviceable in the Gulf of St. Lawrence. The density of the water was taken at the surface only. The variation did not prove sufficient, however, to be relied upon as an indication of direction of movement. The temperature was taken to a depth of 30 fathoms, and more was expected from the temperature than from the density, as it was hoped it would serve to trace the course of the Polar current. The depth of 30 fathoms was found sufficient, as the water was there at the freezing point throughout the region examined, both south and east of Newfoundland, during the whole season from May to September. All the change which took place during the progress of the season or from other causes was between the surface and 30 fathoms. The change of the temperature of the water also afforded an interesting valuation for the amount of wind disturbance, and the depth to which it extended, under given conditions.

Two results were arrived at, which made the temperature observations of little value for the purpose of tracing the movement of the water by its temperature, and which it will therefore be sufficient to mention briefly:—(1) The temperature of the water at 30 fathoms is practically at the freezing point in all parts of this region, from the mouth of Placentia Bay to St. Johns. It varied only from $30\frac{1}{2}°$ to $34°$ F., and there was no change from one month to another, from May to September. (2) The water of the Polar current warms up quite as much on the surface as the surface water elsewhere in this region. The general increase of the surface temperature along the south shore, from St. Pierre to Trepassey, was from $36\frac{1}{2}°$ in May to $50°$ in September, and the surface temperature of the Polar current rose from an average of $34\frac{1}{2}°$ at the end of May to $50\frac{1}{4}°$ at the middle of August. Whether this increase of the surface temperature takes place during the progress of the current southward, or whether this warmer surface water flows over it from elsewhere, we have not sufficiently extended observations to determine. But for the guidance of the mariner, it is evident that the lower temperature cannot be depended on as an indication of the current-belt itself.

A very interesting result was met with, however, on account of the rapid fall in temperature from the surface downwards. The temperature proved to be a valuable indication of wind disturbance. During heavy winds, especially when off-shore, the surface water was driven out to the offing, and the cold under-water came up to the surface. A heavy fall in temperature would thus occur. For example, towards the end of August, the surface temperature over the area from Cape Spear to Cape Race was $50°$. There followed during three days 1312 miles of westerly winds, ranging from north-west to west-south-west, when the surface temperature within three miles of the shore fell to $36°$ and $34°$, and in a belt ten miles wide along the windward shore it was below $45°$. Careful observations and some special runs were made to ascertain the amount of lateral displacement of the current and the depth of disturbance due to a measured mileage of wind. This was done without loss of time, as the weather was then too heavy to carry on work at anchor. Later, when the weather moderated, the temperature again furnished a basis for a very fair estimate of the rate at which the current-belt moved back laterally to resume its usual course.

Ice as an Indication of Current.—To infer the behaviour of a current from the drift of ice with any certainty, the indications given by flat ice and by icebergs must be carefully distinguished. The flat or pan ice runs with the surface current, and is much influenced by the wind, whereas the icebergs indicate the average movement of the body of the water as a whole, and the wind has no appreciable effect upon them. This distinction is well known to sealers, and they habitually take advantage of it. When working against a gale of wind, they will moor their vessel to an iceberg, and lie in its lee while the small ice goes past with the drive of the wind, because, as they express it, the wind takes no hold on an iceberg at all. They thus save a long drift to leeward. It is thus from the icebergs rather than from the flat ice that we can find indications of value.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The following is the text of the speeches delivered by Prof. Love in presenting recipients of the degree of D.Sc. *honoris causa* at the Encaenia, June 22, in the presence of the Chancellor of the university:—

THE HON. CHARLES ALGERNON PARSONS.

Duobus fere millibus abhinc annis Heron Alexandrinus turbinem quemdam per ludum excogitavit, qui vapore calido actus per tubos inflexos afflante converteretur. Carolus Algernon Parsons inter Hibernos nobilissimus, scientiae etiam laude insignis, ita Heronis vestigiis institit ut, quod ille ludendi causa finxerat, ipse in usum nostrum converteret, quo facilius homines naturae imperarent. Optime sane meritus est de omnibus qui urbes habitant, quibus vias et domos luce electrica hoc invento usus illustravit, neque minus profuit Nerea temptantibus, cum his turbinibus impulsae per altum naves celeritate inaudita ferantur recta semper carina adeo ut navigantium incommoda magna ex parte adleventur.

SIGNOR GUGLIELMO MARCONI.

Hic est ille magus, Gulielmus Marconi, qui modum invenit signorum ab ora in oram, a nave ad navem trans maria immensa transmittendorum. Docuerat quidem Maxwell, civis noster, vim electricam per aethera omnia permeantem quasi fluctibus quibusdam perferri. Accessit etiam Hertz, Germaniae ornamentum, qui ostendit quo modo hi fluctus ita regerentur ut tanquam procella quaedam electrica procul exorta aliis in locis satis longinquis agnosceretur. Marconi tandem, qua erat ingenii audacia, id excogitavit ut his subsidiis usus locos disiunctissimos quasi colloquendi quadam facultate coniungeret. Sollertia igitur maxima, patientia vero admirabili praeditus, singula impedimenta quae spei exsequendae obstabant felicissime pervicit, iamque potest nullo vinculo, nullo filo intercedente, quod vel oculi vel tactio deprehendere possint, super dimidiam orbis terrarum partem signa transmittere.

Sir William Selby Church.

Salutat Academia nostra unum ex alumnis suis, olim inter nos artis medicae doctorem, nunc Collegii Universitatis socium honoris causa creatum, Willelmum Selby Church. Academiae etiam personam gessit in communi illo medicorum Britannico consilio, penes quod regimen est examinationum in arte medica habendarum. Multos annos insignis est inter medicos qui mercede vel parva vel nulla accepta egentes in maximis valetudinariis Londinensibus curant: permulti etiam qui hodie in omni parte regni medicinam exercent hoc magistro et auctore studiorum usi sunt. Plurimum auctoritate valet in Regali medicorum Collegio, cui nuperrime Praeses iterum factus est: praemium denique singularium erga artem medicam et cives suos meritorum accepit Baronettus a regina nostra Victoria et Eques de Balneo a rege nostro Edwardo creatus.

Sir Andrew Noble.

Asclepium iure sequitur Mavors, plurium nisi fallor interfector. Ubicunque homines diras illas machinas moliuntur, quae novos bello terrores addiderunt, in honore est Andreas Noble, vir honoribus et insignibus a multis regibus, inter quos noster numeratur, saepe donatus propter operam in omni apparatu bellico praecipuam. Qui cum in exercitu Britannico summa laude meruisset iam rude donatus multos per annos maximae illi prope Tynam officinae praefuit ubi immania Vulcani tela et naves urbis instar habentes in usum nostrum et aliarum civitatum Cyclopes novi fabricantur. Sed quamvis Martis cultor insignis Minervae etiam acceptus est: hoc enim praeter ceteros operam dante et hortante Laboratorium maximum scientiae Physices augendae causa nuper institutum est, novo sane exemplo, unde patet rectores nostros, quantum civium utilitatibus prosit rerum naturalium scientia, aliquando intellegere.

Sir William Crookes.

In multis generibus quaerendi fructus magnos adsecutus est Willelmus Crookes. Ut a Chemia incipiam, novis analyseos modis usus a Kirchhoff et Bunsen in Germania excogitatis, qui substantias a luce quam ardentes emitterent aliam ab alia dignoscerent, ipse novum quoddam elementum, Thallium dico, invenit, prima spolia eademque opima his armis nactus. Eiusdem autem Thallii atomos etiam expendere potuit, quo nihil subtilius, nihil admirabilius. Primus etiam illud divinavit corpora materialia ita posse existere ut neque solida neque liquida neque vapora sint. Hoc demonstravit cum e tubulo aera extraheret donec spatium illud intra tubulum inclusum materia fere omni vacaret. Neque ipse solum in hoc curriculo feliciter versatus est, sed alii ex iisdem carceribus emissi alias palmas reportaverunt. Illud vero non silendum esse arbitror eum, cum de hoc genere quaereret, instrumentum quoddam effinxisse ad vim radiorum solis emetiendam, quod iure omnes inter miracula habent.

Sir David Gill.

In extremo Africae meridionalis promontorio sub tutela navium Britannicarum surgit turris ad siderum motus observandos destinata. Illic plus viginti iam annos magno astronomorum omnium emolumento caeli signa perscrutatus est David Gill. Illic rem quater de integro aggressus id adsecutus est ut distantiam, quae inter solem et nostram terram intercedat, accuratius quam quivis e prioribus emetiretur, adeo ut hodie omnes astronomi eius rationes pro veris habeant. Idem eodem modo distantiam inter solem et quindecim ex stellis, quae fixae vocantur, definivit. Accuratissimam etiam descriptionem fecit earum caeli regionum, quas non nisi Australe latus orbis terrae incolentibus spectare concessum, et in tabulis maximis faciendis, quibus variae caeli partes cura exquisitissima depinguntur, cui operi praeclaro omnes ubique gentes hodie incumbunt, rem felicissime navavit.

Sir John Murray.

Alia ex Colonia transmarina ad nos venit Ioannes Murray, qui quamquam origine Scotus media in Canada et natus et institutus est. De aqua marina, de animalibus mare habitantibus nemo est illo doctior. Harum rerum investigandarum causa navigationes plurimas fecit. Triginta quidem abhinc annos, cum novi quidam Argonautae a rectoribus nostris publice missi sunt, qui ex omni mari materiam scientiae colligerent, ipse inter delectos heroas fuit. Fructus vero illius navigationis quinque et quadraginta magnis commentariorum voluminibus continentur, quibus omnes usi sunt, qui de natura salis, de calore maris, de marinorum animalium formis et agendi rationibus postea scripserunt. Maximas profecto gratias habent omnes qui rerum naturae student Ioannae Murray horum commentariorum editori.

Prof. Alfred Marshall.

Academia nostra particeps est laudis quam adsecutus est Aluredus Marshall. Cum enim in litterarum commercio ea ratione semper uberetur quam hic in rebus venalibus constantissime vindicavit ut amico portu advenas omnes reciperet, hunc virum magno cum fructu inter suos adscivit, quamquam Cantabrigiae olim mathematicae studuit et in eadem Academia nunc Oeconomias Professor est. Primus hic inventus est qui rationibus mathematicis fretus, quae antea tantum ad naturam rerum cognoscendam a physicis adhibitae sunt, de commercio hominum et societate quaereret. Cum in omni analyseos genere doctissimus esset, symbolis tamen parcissime est usus, et diviti cuidam ratiocinandi venae rerum minutissimam cognitionem addidit, unde factum est ut opus illud maximum de Oeconomias principiis non solum scientiae maturae et perfectae artis sed etiam sapientiae altissimae monumentum exstet.

Prof. J. J. Thomson.

Inter Naturae venatores qui experimentis faciendis praecipue incumbunt Iosephus Ioannes Thomson dux est et signifer. Qui rationibus felicissime conceptis id demonstravit, quod nonnulli prius suspicati sunt, atomos illas, e quibus constat materia rerum, e minutissimis quibusdam et fere innumerabilibus corpusculis conglutinatas esse, quae tamen ipse et enumerare et expendere potuit. Neque hoc tantum adsecutus est, sed in vi electrica et magnetica et in natura atomorum cognoscenda se semper exercuit. Nos qui audivimus luculentissimam eius orationem cum nuperrime in hac Academia contionatus est, qui vidimus pulcherrima illa experimenta, quibus rationes suas probavit, minime mirabimur, cum omnes ex omnibus gentibus huius scientiae avidos se Cantabrigiam conferre, tum ex eius fontibus tot discipulos uberrimo cum fructu suos hortulos irrigare.

Prof. Horace Lamb.

Et hic et apud Antipodas summam laudem adeptus est Horatius Lamb, qui et in Academia de Adelaide, cum in Australia versaretur, et Mancuniae in Academia Victoriana mathematices optimos studendi modos ostendit. Neque solum in rebus Academicis gubernandis maxime floret, sed de rationibus physicis secundum mathematicam artem tractandis libros optimos scripsit, quos omnes in manu habent, velut de fluidorum motu, de luce, de vi electrica, de sonitu, de scientia machinali: nuperrime etiam de terrarum motibus luculentissime disseruit. In his operibus ita tenuissima illa analysi, quae mathematicorum propria est, ad rationes physicas expendendas usus est, ut saepe res tenebris ante sepultas nova luce illustraret. Pauci sane hodie sunt qui de tot scientiae generibus egerunt: qui melius et probabilius de ullo scripserit, nemo est.

Prof. A. R. Forsyth.

Scientiam mathematicam qualis hodie est tanquam monumentum esse videtur multorum laboribus multis in terris sensim aedificatum: inter quos locum insignem tenet Andreas Russell Forsyth, non solum quod ipse huic praeclaro operi multos lapides imposuit, sed quod haec omnia quasi calce et caemento conglutinavit. Augustinus Cauchy, Bernardus Riemann, Carolus Weierstrass, hi Germani, ille Gallus, analyseos problemata tribus viis aggressi, quisque pro se summi momenti res reppererant: quae inventa ut in unam rationem congruentem conflaret, ut vinculis et nexibus coniungeret, ut his tribus quaerendi modis usus cognitionis humanae fines promoveret, inventus est Andreas Forsyth. De quo illud affirmare possumus si Fata eum insignem inter mathematicos non fecisset, insignem in re publica gubernanda fecisset Natura, adeo eius consilia in rebus Academicis Cantabrigienses sui petunt, tanti eius iudicium ab omnibus aestimatur.

PROF. J. DEWAR.

Liquidone de aere loquitur quis? Occurrit menti Iacobus Dewar. Quid enim? Partem aliquam aeris circumambientis corripere, secernere in vasculo, cogere ut modo fluat sicut aqua, modo congeletur sicut glacies, nonne haec ultra ingenii humani fines videntur? Quae tamen posse fieri iamdudum notum est: immo, aliquando facta sunt, sed in tenui erat et labor et successus. Ulterius vero progressus est Iacobus Dewar, qui cum neque impensae neque labori neque cogitationibus suis parceret, instrumenta exquisitissima perfecit, quibus vis aliqua maior vel aeris vel tenuissimarum illarum substantiarum ipsum aera subtilitate superantium modo liquida modo solida fiat. Ita nova quaedam et potentissima Naturam investigantibus subsidia, quibus ipse maximo cum fructu usus est, aliis tradidit, cum materia qualis sit omni fere caloris particula ablata homines iam cognoscere possint.

PROF. J. LARMOR.

Newtonus ille, "qui genus humanum ingenio superavit," solem terram lunam planetas nutu quodam et pondere contineri docuit, et motus suos conficere hac vi compulsos. Cui successit his diebus Iosephus Larmor, cathedrae Newtonianae novissimum decus, qui vir ingenio Hibernus, mathematices scientia vere Cantabrigiensis, id fecit ut in omni omnis corporis atomo mundi imaginem expressam videremus, cum doceret particulas minutissimas, e quibus corporum atomi constent, vi electrica contineri et hoc momento coactas quasi per orbitas agitari. Quae doctrina non modo in ordinem convenientem redegit quidquid antea de luminis natura de vi electrica et magnetica compertum est, sed nodos difficillimos, quibus implicantur ii qui experimentis faciendis se totos dant, omnes exsolvit.

AT presentation day of the University of Manchester on July 2, the honorary degree of D.Sc. was conferred on Prof. B. Brauner, of the Czech University of Prague, Dr. Ludwig Mond, F.R.S., and Dr. W. H. Perkin, sen., F.R.S.

THE Schunck Laboratory, which was bequeathed to Owens College by the late Dr. Schunck, and has been removed from his residence at Kersal and rebuilt in the college precincts as nearly as possible in its original form, was formally opened by Dr. W. H. Perkin, F.R.S., last week.

WE learn from *Science* that at the recent commencement exercises of Columbia University a gift of 50,000*l.* from Mr. Lewisohn was announced, to be used for a building for the School of Mines. It is also reported that the sum of 65,000*l.* has been collected for MacAlaster College in Minnesota. The largest gifts were 20,000*l.* from Mr. C. D. Dayton and 10,000*l.* from Mr. J. J. Hill.

THE first volume, January to June, 1904, of *School*, the new educational periodical published by Mr. John Murray, has now been issued. It contains a good supply of articles on educational subjects of theoretical interest which will appeal to the student of pedagogics. Matters of educational administration, and notes on the way in which the recent Education Acts are being utilised by local authorities, are given a prominent place. The teaching of science, and topics of especial interest to those engaged in this part of school work, receive but little attention.

IN connection with the opening of the new laboratories and workshops by Sir William H. White, K.C.B., at the Merchant Venturers' Technical College, Bristol—which was announced in our issue of June 9—the governing body has issued a lavishly illustrated "Souvenir," which provides an excellent account of the work and equipment of the enlarged institution. In tracing the growth of the college during the last fourteen years, the pamphlet shows that during this period the number of adult students attending the day classes has increased five-fold, the number in attendance in 1890 being 48, and this year 242. It is only necessary to read the descriptions of the workshops provided for the technical instruction of printers, bookbinders, painters, plumbers, and engineers of various kinds to appreciate how much is being done in Bristol to train fully qualified workmen for the city's industries, and the large number of students who attend the courses of work provided shows that the men themselves appreciate what is offered. The provision of classes in the branches of science associated with these technical subjects is also satisfactory.

THE recently published "Besuchs-Statistik" for the semester ending in March last shows that there were 37,854 matriculated students studying in German universities, including 3093 foreigners (this is the highest total ever reached by the non-German element); the number of non-matriculated students was 9187, thus making a sum total of 47,041. Of the different universities, Berlin easily stands first with 7503 matriculated and 6353 non-matriculated students. The next in numerical order are Munich with 4609, Leipzig with 3772, and Bonn with 2294 students of all classes. Breslau and Halle have each more than 1500, and the following nine universities more than 1000 students:—Tübingen, Göttingen, Heidelberg, Strassburg, Freiburg, Würzburg, Münster, Marburg, and Giessen. Of the foreign students 2620 are Europeans, consequently leaving 473 who hail from the other continents. Among these 2620 European students, Russia, with 986, sends considerably the largest contingent; then follow Austria and Switzerland. It is a remarkable fact shown by the statistics that by far the largest proportion of non-matriculated to matriculated students, viz. 42 per cent., is to be found in Berlin. The weaker sex, represented at all the universities except Münster, Greifswald, and Rostock, forms a seventh part of the total of non-matriculated students. Berlin claims the largest portion of Germany's lady students, for 42 out of every 100 prefer to study in the Imperial capital, the universities next in favour being Breslau, Bonn, and Strassburg, but here their numbers never exceed 100. The total number of students at the French universities for the semester ending in March was 30,405. Here again the university in the capital easily heads the list with 12,948 students. Then come Bordeaux, 2320; Toulouse, 2191; Montpellier, 1707; Nancy, 1327; Rennes, 1190; Lille, 1164; Aix-Marseille, 1080; Dijon, 880; Poitiers, 863; Caen, 752; Grenoble, 705; Besançon, 333; and Clermont, 299. 10,972 belonged to the law faculty, 6686 to the medical, 4765 to the science, 4384 to the arts, 3014 to the "pharmaceutical" faculty. The numbers of foreigners, amounting to nearly 2000, included 450 Russians, 200 Persians, 175 Roumanians, 165 Germans, 109 Bulgarians, 113 Turks, 83 Egyptians, 57 Americans, and 35 English students. The sum total of women students amounted to 1125, of whom 677 were of French nationality and 448 foreigners—almost entirely of Russian birth.

THE Senate of the University of London, at a meeting on June 28, considered a report from the committee appointed to deal with the offer of the Goldsmiths' Company to transfer to the university the Goldsmiths' Institute at New Cross. The Senate decided to accept the munificent offer of the company, and an *ad interim* committee was appointed to carry out the reorganisation of the institute. To meet the needs of the county councils of London, Middlesex, Kent, and Surrey, and the borough council of Croydon, it is proposed that a day training college for about 400 students shall be opened in the Goldsmiths' Institute in the autumn of 1905. In connection with this college it is considered important that day classes should be held preparatory for the intermediate examinations, or up to the standard of the intermediate examinations, in arts and science. This scheme will absorb the funds at the disposal of the university, which will thus be unable to carry on other classes unless it receives further financial support. Should such support be forthcoming, it is prepared to carry on at New Cross the higher part of the work of a polytechnic, and to continue the existing school of art. It will not be possible for the university to continue the social and recreative side of the institute. The scheme has received the full approval of the Goldsmiths' Company. The Education Committee of the London County Council has also had the affairs of the Goldsmiths' Institute under consideration, and on Tuesday the council accepted its recommendations to inform the Goldsmiths' Company that the council would view with regret the closing of the Goldsmiths' Institute and the termination of its educational work as a polytechnic, and inviting the company to consider whether some arrangement cannot be come to by which the work of the institute could be con-

tinued in its present polytechnic form. Another recommendation accepted states, among other points, that, in the event of its proving impossible to secure the continuance of the Goldsmiths' Institute as a polytechnic, the council would regard it as of great importance to secure its retention as a centre of evening instruction in as many subjects as possible, especially in the higher grades, and to arrange for the continuance of an efficient department of mechanical and electrical engineering for evening students.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 9.—"The Fossil Flora of the Culm Measures of North-west Devon, and the Palæobotanical Evidence with regard to the Age of the Beds." By E. A. Newell **Arber**. Communicated by Prof. McKenny Hughes, F.R.S.

The Carboniferous rocks of Devonshire, generally known as the Culm Measures, are divided into an Upper and a Lower division. The Upper Culm Measures, which are of Upper Carboniferous age, form by far the thickest portion of this Carboniferous series. Plant remains, although abundant in these beds, are rarely sufficiently well preserved to admit of identification. A number of species have, however, been obtained, some of which are new to Britain, from the one horizon in the Upper Culm Measures in which coal, known locally as culm, is found. This flora is identical with that of the Middle Coal Measures elsewhere in England, and consequently the horizon on which the coal or culm occurs in the Bideford district is the equivalent of the Middle Coal Measures, a higher horizon than has been previously assigned to these beds.

There is also evidence that the Culm Measures at Instow, which occupy a lower horizon than the Culm Measures of the Bideford district, are probably the equivalents of the Lower Coal Measures. Thus both the Lower and Middle Coal Measures are represented in Devonshire, and, as the higher beds of the Culm Measures are as yet unexplored, possibly even higher horizons may eventually be found to be represented.

It is pointed out that the Culm Measures of Devon, which have been regarded by several geologists as essentially a Lower Carboniferous formation, are in reality chiefly, but not entirely, of Upper Carboniferous age. Consequently, the term "culm" or "kulm" generally applied to certain deposits in Germany, Austria, and elsewhere on the Continent, which are entirely of Lower Carboniferous age, is peculiarly unfortunate, for these beds are not of the same age as the great bulk of the Devonshire Culm Measures.

June 16.—"The Decomposition of Ammonia by Heat." By Dr. E. P. **Perman** and G. A. S. **Atkinson**.

Ammonia gas was heated in a porcelain globe placed in a muffle furnace, and the total pressure of the ammonia and decomposition products was read by means of a mercury manometer at equal time intervals, the volume being kept constant. The temperature was measured by a Callendar-Griffiths pyrometer, and was maintained constant within 1° or 2°; in the various experiments it varied from 677° to 1111°.

At the end of each experiment the temperature was raised to about 1100°, and maintained at that point until the decomposition of the ammonia was practically complete; the pressure was then read again, and from it was calculated the initial pressure of the ammonia in the globe.

Let p_1 be the pressure of the ammonia at any instant during the decomposition, p_1' that of the nitrogen, p_2' that of the hydrogen, P the total pressure at the same instant, p_0 the initial pressure of the ammonia, then $p_1+p_1'+p_2'=P$, $p_2'=3p_1'$, and $p_1'+p_2'=2(p_0-p_1)$; from these equations it follows by substitution that $p_1=2p_0-P$, *i.e.* the pressure of the ammonia at any instant is double the initial pressure minus the total pressure at the instant of observation. The experimental data furnish values of P and $2p_0$, and values of $2p_0-P$ have been calculated and tabulated; from the latter were calculated $\Delta P/\Delta t$; but $\Delta P/\Delta t=dP/dt$ approximately, and $dP/dt=dp_1/dt$, so that the rate of change of pressure of the ammonia at various pressures becomes known. Two series of curves have been drawn showing the variation of the rate with the pressure. The most noteworthy features of the curves are:—(1) at the highest temperatures they become straight lines; (2) they all run towards the origin; (3) they become much steeper when certain metals (mercury, iron, or platinum) are present in the globe. The chief deductions are:—(1) the decomposition is monomolecular; (2) and (practically if not completely) irreversible; (3) the rate of decomposition is much increased by the presence of certain metals.

Some experiments were made also on the effect of sudden change of pressure on the rate of decomposition; the results confirmed the conclusion that the reaction is monomolecular. The irreversibility of the reaction was confirmed by passing nitrogen and hydrogen through a red-hot glass tube containing porcelain, when no ammonia was found to be produced.

Royal Astronomical Society, June 10.—Prof. H. H. Turner, president, in the chair.—Mr. A. R. **Hinks** read a paper on the reduction of 295 photographs of Eros made at nine observatories during the period 1902 November 7–15, with a determination of the solar parallax; 110 of the plates were taken at Cambridge, the remainder at Algiers, Lick Observatory, Northfield Observatory, Oxford, Paris, and other observatories. The author described the method employed in the reductions, &c., and gave as the resulting value for the solar parallax $8''.7966 \pm 0''.0047$, a result nearly in accordance with that obtained by Sir D. Gill from heliometer observations of minor planets.—Mr. M. E. J. **Gheury** read a paper on the gyroscopic collimator of Admiral Fleuriais. In this instrument the principle of the gyroscope was employed to furnish an artificial horizon for sextant observations at sea. The instrument was shown to the meeting, and its construction and method of employment were described.—Mr. Bryan **Cookson** gave an account of his paper on the mass of Jupiter, and corrections to the elements of the orbits of the satellites, from heliometer observations made at the Cape Observatory during the years 1901 and 1902. The methods of observation and reduction were explained, and a brief account given of the results.—Mr. E. W. **Maunder** read a paper on the distribution of sun-spots in heliographic latitude during the years 1874 to 1902. The author considered Spoerer's law for the distribution of sun-spots to be true within the limits of its enunciation—that there is only one spot zone in either hemisphere except during the brief period just after minimum.—The Rev. A. L. **Cortie** read a paper on the variation of latitude of the greater sun-spot disturbances, 1881–1903. Dr. Lockyer briefly replied, contesting some of Mr. Maunder's conclusions.

Chemical Society, June 15.—Prof. W. A. Tilden, F.R.S., president, in the chair.—The following papers were read:—The mechanical analysis of soils and the composition of the fractions resulting therefrom: A. D. **Hall**. The object of the investigation was to ascertain the effect of introducing into the mechanical analysis of soils a preliminary treatment of the soil in dilute acid followed by ammonia, as first suggested by Schlœsing. Eighteen soils of known history were selected from the Rothamsted experimental plots, to give comparisons of the same soil in an unmanured condition and when rich in humus through the accumulation of organic matter. With these soils the method involving a preliminary treatment with acid showed the essential identity of soils from the same experimental field whatever the manuring had been, whereas the analyses made on the raw soil gave very different results, depending on the treatment the various plots had received.—The effect of the long-continued use of sodium nitrate on the constitution of the soil: A. D. **Hall**. On reviewing the results of the mechanical analysis of the Rothamsted soils, it was observed that those which had been manured with sodium nitrate every year gave abnormal results for the last fraction. The removal of the finest particles from the surface soil is attributed to deflocculation induced by the use of sodium nitrate, and followed by the washing of the finest particles into the subsoil.—The decomposition of oxalates by heat: A. **Scott**. It is shown that the decomposition of oxalates by heat is less simple than is generally supposed, and that, except in the case of magnesium oxalate, the oxalates of the common metals generally yield a small

quantity of carbon.—Some alkyl derivatives of sulphur, selenium and tellurium: A. **Scott**. A description of the derivatives obtained by the action of various alkyl iodides on these elements.—The ultra-violet absorption spectra of certain *enol-keto*-tautomerides, part i., acetylacetone and ethyl acetoacetate: E. C. C. **Baly** and C. H. **Desch**. From comparative observations of the absorption spectra of these compounds under various conditions, the conclusion is drawn that with acetylacetone, ethyl acetoacetate, and their metallic derivatives, a state of dynamic isomerism exists in the solutions, and that this isomerism is evidenced by a characteristic band in the spectra.—The action of acetyl chloride on the sodium salt of diacetylacetone and the constitution of pyrone compounds: J. N. **Collie**. A description of three isomerides obtained in this reaction, from the study of which the author has been led to assign a new constitution to pyrone and its derivatives.—Our present knowledge of the chemistry of indigo: W. P. **Bloxam**. Some observations on the purity of commercial indigotin and on the composition of indirubin were made.—$\Delta^{1:3}$-Dihydrobenzene: A. W. **Crossley**. A description of the formation and properties of this substance is given.—The absorption spectrum of *p*-nitrosodimethylaniline: W. N. **Hartley**. The absorption caused by *p*-nitrosodimethylaniline at the less refrangible end extends into the infra-red, and at the more refrangible far into the ultra-violet. The transmitted rays are thus restricted to a band of yellow and green light bordered on either side by a band of intense absorption. The alkyl-substituted phenols and anilines absorb varying quantities of the ultra-violet, the absorption not extending into the visible spectrum; but it is also shown that the introduction of the NO, as distinguished from the NOH group, extends the absorption far into the coloured rays.—The influence of solvents on the rotation of optically active compounds, part vi., the relationship between solution-volume and rotation of the dialkyl and potassum alkyl tartrates in aqueous solution: T. S. **Patterson**.—The constitution of hydrastinine: J. J. **Dobbie** and C. K. **Tinkler**. Solutions of hydrastinine in ether or chloroform are colourless, and their absorption spectra are practically identical with the spectra of hydrohydrastinine. From this it is argued that the carbinol formula should be preferred to the open-chain or aldehydic formula of Roser. On the other hand, the aqueous or alcoholic solutions of hydrastinine give spectra which agree with those of the hydrastinine salts, whence it would appear that, under the influence of these solvents, hydrastinine changes from the carbinol to the ammonium base.—The influence of moist alcohol and ethyl chloride on the boiling point of chloroform: J. **Wade** and H. **Finnemore**. Chloroform made from alcohol contains, in addition to alcohol, a small quantity of ethyl chloride, both of which depress the boiling point.—Limonene nitrosocyanides: W. A. **Tilden** and F. P. **Leach**. The nitrosocyanide described by Tilden and Burrows as a liquid is found to be a crystalline optically active solid having m.p. 90–91°, and $[\alpha]_D + 165°$.—Photochemically active chlorine, ii., a preliminary notice: C. H. **Burgess** and D. L. **Chapman**.—Additive compounds of anhydrous magnesium bromide with organic oxygen and nitrogen compounds: J. J. **Sudborough**, H. **Hibbert**, and S. H. **Beard**.—Differentiation of primary, secondary, and tertiary amines. A preliminary note: J. J. **Sudborough** and H. **Hibbert**.—Influence of radium radiations on labile stereoisomerides: J. J. **Sudborough**. The results indicate that *allo*-cinnamic acid and its α and β bromo-derivatives are transformed more readily under the influence of sunlight than by prolonged exposure to radium radiations.—Notes on analytical chemistry: G. T. **Morgan**. The separation of arsenic by distillation in hydrogen chloride. The estimation of carbon by oxidation with chromic acid.—Nitrogen chlorides containing two halogen atoms attached to the nitrogen: F. D. **Chattaway**.—Sulphonphenylchloroamides and sulphontolylchloroamides: F. D. **Chattaway**.—Stereoisomeric glucoses and the hydrolysis of glucosidic acetates: E. F. **Armstrong** and P. S. **Arup**. It was shown that the acetyl groups are removed with unequal readiness from the penta-acetates of glucose and galactose and from sucrose octaacetate, and with equal readiness from the tetra-acetates of the methylglucosides and galactosides.—The colouring matter of the flowers of *Butea frondosa*: A. G. **Perkin**. This dye-stuff is shown to contain two substances, *butin* and *butein*, which are closely related in constitution, the former being a chalkone compound and the latter the corresponding flavonone isomeride.—Cyanomaclurin: A. G. **Perkin**. This product, which exists in jackwood, closely resembles the catechins in constitution, and is probably derived from them by the replacement of a catechol nucleus by resorcinol.—The determination of acetyl groups: A. G. **Perkin**. A description of a hydrolytic method of estimating acetyl groups in organic compounds.—Note on the catechins: A. G. **Perkin**. A description of the acetyl derivative of the catechin (*acacatechin*) derived from *Acacia catechu* is given.—A constituent of Java indigo: A. G. **Perkin**. It is shown that the yellow colouring matter present in Java indigo is identical with kampherol.

Royal Microscopical Society, June 15.—Dr. D. H. Scott, F.R.S., president, in the chair.—A direct proof of Abbe's theorems on the microscopic resolution of gratings: Prof. J. D. **Everett**. The image of the grating formed by the objective is the resultant effect of the disturbances in the image plane due to the diffraction spectra formed in the focal plane. The optical path measured from a plane wave-front, before incidence on the grating, to the spectrum of order 0, is unaffected by displacement of the grating. The path to a spectrum of order 1 is altered by $\lambda x/s$, and to a spectrum of order n by $n\lambda x/s$, by a shift x of the grating, s denoting the distance between rulings. At a fixed point P in the image plane, the interference of the spectrum of order 0 with a spectrum of order n goes through a complete cycle, while x increases by s/n. That is, n lines in the image move across P during a displacement s of the grating. Similar reasoning applies to the interference of any two of the spectra, and gives Abbe's results. A displacement x towards either side diminishes the paths to the spectra on this side, and increases the paths to the spectra on the other side. When only one spectrum operates, there is no interference and no alternation of brightness.—The recent Foraminifera of the Malay Archipelago: F. W. **Millett**.—Nature's protection of insect life: F. **Enock**.

Physical Society, June 24.—Dr. R. T. Glazebrook, F.R.S., president, in the chair.—Chemical dissociation and electrical conductivity: A. E. **Garrett** and Dr. R. S. **Willows**. It has been shown by Beattie (*Phil. Mag.*, 1899) that a mixture of salt and iodine, when placed on a zinc plate and heated, gives rise to electrical conductivity, although separately no such effect is produced. This is shown to be due to the formation of zinc iodide. Following on this the electrical conductivity produced by heating various salts is investigated under different conditions of temperature and electric field. A large excess of positive electricity is found in nearly every case.—The magnetisation of iron in bulk: Dr. W. M. **Thornton**. The paper is in three sections. The first describes a method of measuring large quantities of magnetism by the use of an exploring coil placed around the core and an exciting coil in series with a recording milli-voltmeter. The second section deals with the curves of rise of magnetising currents, when the core is solid and when laminated, as affected by the reaction of the core-currents, and also by the change of permeability during magnetisation. In the last section an example is given of the sudden dip in the curve of rise observed only with large cores.

PARIS.

Academy of Sciences, June 27.—M. Mascart in the chair.—Researches on cyanogen: solubility and polymerisation: M. **Berthelot**. There is no true coefficient of solubility of cyanogen in water or alcohol, a slow chemical reaction taking place from the first. With other solvents, such as acetic acid, turpentine, chloroform, and benzene, the ordinary laws of solution are obeyed.—Researches on cyanogen and on its reaction with potassium cyanide: M. **Berthelot**. An attempt to prepare polycyanides corresponding to the triiodides was not successful. Cyanogen is rapidly absorbed by a solution of potassium cyanide, but no compound corresponding to potassium triiodide was obtained, the gas being partly hydrolysed and partly polymerised.—On the distribution of time at a distance by means of wireless telegraphy: G. **Bigourdan**. The experiments described have been successful up to a distance of 2 kilo-

metres, and there seems no reason to suppose that the signals could not be easily sent over much longer distances.—On the distillation of a mixture of two metals: Henri **Moissan** and M. **O'Farrelley.** Alloys of copper, lead, zinc, cadmium, and tin were heated in carbon boats in the electric furnace. The alloys behaved exactly as in an ordinary fractional distillation, the composition varying with the time of distillation and the quantity of metal distilled. Thus with alloys of zinc and copper, cadmium and copper, lead and copper, a residue could be obtained after a certain time consisting of pure copper.—The influence on the rotatory power of certain molecules exerted by non-saturated radicals. The allyl ethers of borneol, menthol, methylcyclohexanol, and linalool: A. **Haller** and F. **March.** With one exception, the ethers possess a higher rotatory power than the active alcohols from which they are derived. With the same exception, the molecular refractive powers found are in accord with those calculated.—Muscular work and the expenditure of energy in dynamic contraction: A. **Chauveau.**—Improvements in the photographic method for recording the action of the *n*-rays on a small electric spark: R. **Blondlot.** The improvements on the method previously described include the use of an aluminium lens for concentrating the rays from the Nernst lamp on the spark gap, together with some details necessary for the working of the spark. Very slow development of the negative is required to bring out the effect clearly.—The action of magnetic and electric forces on ponderable emission; the effect of air in motion on this emanation: R. **Blondlot.**—M. Maquenne was elected a member of the section of rural economy in the place of the late M. Duclaux, and Prof. Waldmeyer a correspondant in the section of anatomy and zoology in the place of Prof. A. Agassiz, elected foreign associate.—On certain classes of isothermal surfaces: L. **Raffy.**—On a class of partial differential equations of the second order: J. **Clairin.**—Remarks on the propagation of percussions in gases: E. **Jouguet.**—On a new aërial helix: H. **Hervé** and H. **de la Vaulx.**—The dielectric cohesion of the saturated vapour of mercury and its mixtures: E. **Bouty.** The experiments were made in a fused silica flask, which satisfied the necessary condition of possessing no conductivity at the temperature of the experiment. The cohesion of mercury vapour is only 0·85 that of air, which, having regard to the high density of the vapour, is remarkably small. The effect of introducing various gases with the mercury vapour was also studied.—The transport of ultramicroscopic particles in the current: A. **Cotton** and H. **Mouton.**—On a new method of three-colour photography: R. W. **Wood.**—On the yellow and red varieties of thallium iodide and the determination of the normal point of their reciprocal transformation: D. **Gernez.** The transition point was determined as 168°, or 22° lower than the figure usually accepted.—On the nitrate and nitrite of thallium: U. **Thomas.** Thallous nitrate is decomposed at 450°, furnishing nitrous anhydride and a well crystallised sesquioxide, without any appreciable amount of nitrite being formed. The nitrite is decomposed in an analogous manner. It was found that thallous nitrate can be partly volatilised without decomposition.—The total synthesis of rhodinol, the characteristic alcohol of essence of roses: L. **Bouveault** and M. **Gourmand.** Ethyl geraniate, treated with sodium and absolute alcohol, gives a mixture of two alcohols, one of which is rhodinol. This alcohol possesses a strong odour of roses, and, except that it is inactive, shows all the properties of the rhodinol extracted from essence of roses and essence of pelargonium. A crystalline semicarbazone, melting at 112°, has been prepared from its pyruvate, and this has been found to be identical with the similar compound prepared from the natural rhodinol.—On two homologues of pyrocatechol: R. **Delange.** The preparation of ethylpyrocatechol and isopropylpyrocatechol is described, and their physical properties given.—On a new class of ether-oxides: Marcel **Descudé.** By the action of sodium ethylate upon dichloromethylether, the ether

$$C_2H_5—O—CH_2—O—CH_2—O—C_2H_5$$

is obtained. In its chemical and physical properties it approximates to the formals.—On methylarsenic: V. **Auger.** Solutions of sodium methylarsenate reduced by heating in the water bath with sodium hypophosphite give a yellow oil of the empirical composition CH_3As. This can be purified by fractional distillation in a vacuum, and cryoscopic determinations in benzene solution show that its molecular weight is four times that of the simple formula. It polymerises readily in presence of hydrochloric acid, giving a brown powder which has been mistaken for arsenic.—On some mixed phosphorus acids derived from hypophosphorous acid: C. **Marie.**—Additional ammoniacal compounds of the rosanilines: Jules **Schmidlin.**—Study of the variation of the mineral matters during the ripening of seeds: G. **André.**—Researches on plant acidity: Eug. **Charabot** and Alex. **Hébert.**—The action of heat and acidity on dissolved amylase: P. **Petit.** The diastatic power of a malt may be increased by altering the acidity of the solution to the point corresponding to coagulation by heat.—Abnormal developments independent of the medium: C. **Viguier.**—On an unknown animal met with in the Bay of Along: M. **L'Eost.** An account of an animal, apparently a sea serpent, seen from the gunboat *Décidée* on February 25. Its length was estimated at 30 metres.—The complete extraction of water and gases from seeds: Paul **Becquerel.**—A resonance method for the determination of the frequency of nervous oscillations: Augustin **Charpentier.**—On the urinary chromogen due to subcutaneous injections of skatol: Ch. **Porcher** and Ch. **Hervieux.**—The action of salts of the alkaline metals upon the living substance: N. C. **Paulesco.** The limiting quantities of salts of the alkalies which act upon yeast under fixed conditions are proportional to their molecular weights.—On the problem of "statical work": hydrodynamical and electrodynamical paradoxes: Ernest **Solvay.**—On the laws of the so-called "statical work" of muscle: Ch. **Henry.**—On the toxic action of intestinal worms: L. **Jammes** and H. **Mandoul.**—Observations at the Franco-Scandinavian captive balloon station at Hald: L. Teisserenc **de Bort.**

CONTENTS.

THURSDAY, JULY 14, 1904.

IS RADIUM AN ELEMENT?

Radio-activity. By Prof. E. Rutherford, F.R.S. Pp. viii + 399. (Cambridge: University Press, 1904.) Price 10s. 6d. net.

Radio-activity. By F. Soddy, M.A. (The *Electrician* Printing and Publishing Co., 1904.)

Radium. By L. A. Levy and H. G. Willis. (London: Percival Marshall and Co., 1904.)

IN February, 1896, M. Henri Becquerel found that uranium salts emit rays capable of affecting a photographic plate and of penetrating black paper and other bodies opaque to ordinary light. In the eight years which have elapsed since, a startling series of discoveries of extraordinary interest to the physicist and chemist has rewarded those experimental investigators who followed up the clue given by Becquerel's observation just mentioned. As the result of their labours, a new branch of physical chemistry has been created which already possesses a bulky literature, growing with ever-increasing velocity. The following are approximately the number of papers on radio-activity published in scientific journals for each year since Becquerel's original discovery:—1896, 7; 1897, 6; 1898, 7; 1899, 18; 1900, 39; 1901, 36; 1902, 41; 1903, 90. Thus at present the literature of the subject comprises several hundred papers, and new papers are appearing at the rate of several per week.

Among those who have contributed most to the exact study of radio-activity, Prof. Rutherford occupies a foremost place, so that a connected account of the experimental results obtained and theories proposed to explain them from his pen cannot but be welcomed by all those interested in the subject. The volume under consideration is the third of the "Cambridge Physical Series," edited by Mr. F. H. Neville, F.R.S., and Mr. W. C. D. Whetham, F.R.S. The first volume was "The Theory of Solutions," by Mr. Whetham, and the second "The Conduction of Electricity through Gases," by Prof. J. J. Thomson. The remarkably high standard of scientific excellence set by the first two volumes of the series is fully maintained by Prof. Rutherford in the third.

The first chapter contains an historical account of the discovery of the radio-active properties of uranium and thorium, of Madame Curie's magnificent discovery of radium, and of the discovery of the other less known radio-active elements. The second chapter contains a short account of the ionization theory of conduction through gases, on which so much of the work on radio-activity depends, and the third a very useful account of the experimental methods employed in investigating the properties of the radiations emitted by the radio-active substances. The remaining chapters contain a very complete and concise account of the nature of the radiations, of the amount of energy emitted, and of the remarkable atomic transformations of radio-active matter. The book is not of a popular character; it is intended for those who wish to study the subject scientifically, possibly with the view of undertaking research work on it. For such students it is admirably adapted, and possible openings for research work are suggested implicity or explicitly on almost every page. Such a work cannot fail to be of great service to scientific students.

The remarkable phenomena exhibited by the radio-active elements have led to the adoption of theories which a few years ago would have appeared almost ridiculous. One gram of radium gives out more than 800,000 gram calories of heat per year. This heat is apparently due to the spontaneous disintegration of radium atoms into matter possessing less energy. Radium is, in fact, an endothermic compound in process of decomposition. So far as we know the process is not reversible, but it may be that at extremely high temperatures radium atoms could be formed by the combination of their products of disintegration with absorption of heat.

The radium atom first emits an α-particle which is a positively charged body having a mass about twice that of a hydrogen atom. The rest of the atom constitutes radium-X. The radium-X then disintegrates into an α-particle, and the gaseous radium emanation, this in turn disintegrates, and the process goes on through a whole series of transformations. The final product is, it is suggested, perhaps polonium. A radium atom, therefore, appears to consist of a polonium atom, and about six α-particles. But there is reason to believe that the α-particles, when their charge is neutralised by a negative corpuscle, become helium atoms. If this is so, then a radium atom is really the compound radical $PoHe_6$, and is not an elementary atom at all. On the other hand, radium is from the chemical standpoint closely analogous to calcium, strontium, and barium, and it finds a place in the periodic arrangement of the elements. If, then, radium is really a compound radical, it is probable that all the other elements, except, perhaps, helium, and a few others of small atomic weight, are compound radicals also. The chemist must, in fact, either adopt a new definition of an element or else prepare for a large reduction in the number of such bodies.

The velocity of the radio-active processes is independent of the temperature. This remarkable fact is said to indicate that the changes taking place are of a purely atomic character. It must be admitted that the meaning of this statement is not very clear. If the radium atom consists of several parts which are separated during the process of disintegration, then the radium atom is really a molecule, and its disintegration is, strictly speaking, a molecular process. Moreover, molecular processes are known the velocity of which is independent of the temperature within certain limits. For example, the rate of solidification of many supercooled liquids increases at first with the supercooling, but then attains a constant value independent of the supercooling over a considerable range of temperature. The energy set free during radio-active processes is enormous compared with the kinetic energy of the molecules due to heat motions, and there is no known reason why such irreversible decompositions should not proceed at a rate independent of the temperature, even if they are not of a purely atomic character.

The rate of disintegration of the radio-active bodies is also independent of their state of chemical combination, which indicates that the radio-active properties belong entirely to the so-called atom of the radio-active element present, and are not communicated to the other atoms present in the compound.

It thus appears that the atoms of the so-called elements contain an immense store of energy, and this discovery leads to interesting possibilities which Prof. Rutherford discusses in connection with the heat supply of the sun and earth, and other heavenly bodies. If the sun and earth draw their heat-supply from this store, then it is possible that the present rate of emission may have been going on for vastly longer ages than those hitherto supposed possible, longer even than the ages demanded by geologists for the completion of the processes of formation of the earth's crust.

Exception may be taken to the terminology adopted in some parts of the book. For example, the product of decomposition of the radium emanation which is deposited on solid bodies is referred to as "emanation-X." It would probably be better to reserve the term emanation for radio-active gases; but at the same time, it must be admitted that "emanation-X" is a better name than "induced radio-activity."

The arrangement of the matter and its treatment are throughout admirable.

Mr. Soddy's book on radio-activity contains an excellent and interesting account of the subject. The arrangement of the matter and point of view adopted are very similar to those in Prof. Rutherford's book, of which Mr. Soddy's is practically an abridged and slightly popularised edition.

Messrs. Levy and Willis's book on radium is supposed to be of a popular character, and contains an account of many of the properties of radio-active bodies. The arrangement of the matter cannot be commended, and the authors' scientific knowledge does not appear to have been sufficient for the task they have undertaken. Facts and results which it is suggested might be obtained if looked for are mixed up in a manner calculated to confuse the reader; there are besides many inaccurate statements. It is difficult to see what useful purpose this book can serve.

HAROLD A. WILSON.

BOOKS ON PLANT-PHYSIOLOGY.

The Physiology of Plants, a Treatise upon the Metabolism and Sources of Energy in Plants. By Prof. W. Pfeffer. Second fully revised edition. Translated and edited by Dr. Alfred J. Ewart. Vols. i. (pp. xii + 632) and ii. (pp. viii + 296). (Oxford: at the Clarendon Press, 1900 and 1903.)

Vorlesungen über Pflanzenphysiologie. By Prof. Ludwig Jost. Pp. xiii + 695; with 172 illustrations. (Jena: Gustav Fischer, 1904.) Price 13 marks.

PROF. PFEFFER is to be congratulated on the completion of his great task—the re-writing, in the form of a second edition, of his well known "Pflanzenphysiologie." The present edition, of which the first instalment appeared in 1897, consists of what are practically three volumes containing some 1600 pages. Of these, the two first volumes are before us in an English translation.

The book is a unique one, for it is certain that none has ever appeared giving so complete an account of the physiology of plants. It must be remembered, too, that during the past forty years this branch of science has, through the labours of Sachs, Pfeffer, and a crowd of other workers, made great advances, and has developed into a huge mass of inter-related problems, so that the subject-matter is far more extensive than that which any previous writer has had to deal with. To form some notion of the activity of this department of botany, it is sufficient to look at the references which crowd the pages of the book.

It is perhaps owing to the mass of new matter which had to be incorporated that Pfeffer has somewhat condensed his presentment of general results. This has some disadvantages, inasmuch as the reader misses the give and take of a full discussion. He gets, it is true, the matured judgment of the author, but he gets it condensed to a somewhat dry and cold essence in which the quality of attractiveness is sacrificed. In what forms the main tissue of the book—the detailed consideration of experimental evidence—Pfeffer is at his best, and rules his armies of facts with the easy authority of one who is not only deeply learned, but experienced at first hand with every part of his subject.

The book follows the broad natural division of the subject into "Stoffwechsel" and "Kraftwechsel," that is, into one volume on metabolism—roughly speaking, nutrition—and two volumes on growth, movement and development. The most notable new feature in vol. ii. of the English edition is the prominence given to "causes of specific shape"; this change is the natural outcome of the recent increase of interest in this field of work, for instance in the researches of Vöchting, Goebel, Klebs, Driesch, &c. In consequence of the greater space given to this department (in itself a decided improvement in the new edition), the attention given to the special physiology of growth is relatively diminished as compared with the old edition. The volume also contains short discussions on heredity, variation, and allied questions. It is useful to know the author's views on questions of fundamental importance, but apart from this consideration we doubt whether these sections are quite worth giving in a book of this character, since it is impossible for the author to give space for an amount of discussion such as the problems demand. However this may be, and such points are largely a matter of individual opinion, on the main point there can be no doubt; no one can question the value of such a mass of information grouped in logical sequence, connected by the thoughts and criticisms of the leading plant-physiologist of the present day, and representing the mature result of a long life of strenuous and successful work.

Dr. Ewart, who has made the English translation, is well qualified for the work, being an accomplished physiologist, and his occasional remarks added in the capacity of editor are of value. The task of translating German requires a certain courage as well as

skill; the original sentences have to be individually annihilated before endurable English equivalents can be raised from their ashes. This Dr. Ewart has done so well that the book reads as though it had been written in English.

No one can nowadays write a physiological textbook without being largely indebted to Pfeffer's "Pflanzenphysiologie," and this, in his preface, Prof. Jost acknowledges in the fullest way; but his book is so different from Pfeffer's in scope and manner of presentment that it is essentially an original work.

It is an eminently readable and useful book; it is written in a clear and easy style, and steers a skilful course between some of the difficulties that beset the lecturer. On the one hand the author avoids placing too much stress on what is new, while he by no means neglects the recent literature, and is thoroughly up-to-date in his treatment of the subject. He is not afraid of facing a difficulty or of pointing out where our knowledge fails to solve the problem. He has produced a book admirably suited to the advanced student of an English university, and one that may also be read with advantage by more advanced workers. Jost's manner of stating his case is so suggestive, and he is so open in pointing to possible lines of inquiry, that the book cannot fail to be useful to a wide class of readers.

It is divided into three parts:—(1) Stoffwechsel, (2) Formwechsel, (3) Energiewechsel. Part i. deals with the absorption, transport, and loss of water, with the assimilation of carbon and nitrogen, and with respiration and fermentation. Under Formwechsel (part ii.) we have a general statement of the fundamental problems of development, then come growth and development under constant conditions. This is followed by the effects of the environment on growth, &c., and finally comes a section on periodicity, inheritance, and variation. Part iii. (Energiewechsel) deals with hygroscopic movements, growth-curvatures ("tropisms"), the movements of tendrils, of sleeping plants, &c., and chemotaxis, &c. The whole of part iii. seems to us particularly good, and contains much that is interesting and valuable in the way of discussion. We confidently recommend Prof. Jost's lectures, but since it is the duty of the reviewer to find some fault, we may direct attention to Fig. 141, which is printed upside down.

F. D.

CHRONOLOGICAL CALCULATIONS.

Astronomical and Historical Chronology in the Battle of the Centuries. By William Leighton Jordan, F.R.G.S., F.S.S., &c. Pp. 70. (London: Longmans and Co., 1904.) Price 2s. net.

THE main object of this little work is to contend that what is sometimes called the "astronomical" method of dating events prior to the Christian era is really what was intended to be used when the system of using dates before and after the birth of Christ was first introduced. Hence it is dedicated to the librarians of the cities of Florence and Pisa, in the hope of receiving from some of them "further evidence for the elucidation of the subject."

Now divisions of this kind involve the drawback of necessitating a reckoning in two directions. This is also the case, for instance, in the centigrade division of the thermometric scale, which is nearly always avoided by the general public in this country, and would be still more in countries which are nearer the equator, by using Fahrenheit's scale, the zero being below the lowest point usually reached in winter, so that a statement of the reading is sufficient, without adding above or below freezing, as the case may be. In dating an event, too, by Christian chronology, we have to state whether it occurred before or after the birth of Christ (or the year accepted as such), which is indicated by affixing the letters B.C. or A.D. But there is this further complication, as compared with a thermometric or other scale, that a degree is a definite point, and everybody knows that 1° below freezing is two degrees below 1° above it. A year is not a definite point of time, and we all know (having had a recent instance of it) what perplexity is caused in many minds when a new century has commenced with regard to which is the first year thereof. Our author reminds us, for instance, how the German Emperor insisted that the present (twentieth) century began at the beginning of the year 1900. A further complication is contained in the fact that we do not know exactly the date of Christ's birth.

But although that question is very interesting from an historical point of view, it is too late now to treat of it as a matter affecting our system of chronology. This is based on the assumed fact that the traditional date of the birth of Christ is the end of the year B.C. 1, so that one year after it was completed at the end of A.D. 1, a century at the end of A.D. 100, nineteen centuries at the end of A.D. 1900, and the twentieth century commenced on January 1, A.D. 1901.

Some people not versed in chronological calculations fancy that astronomers go out of their way to differ from ordinary people when they call the year which is commonly reckoned B.C. 1 (the year preceding A.D. 1) 0, and denominate B.C. 2 as the year − 1. But there is no such affectation of singularity in the matter; a necessity is laid upon the computer in this respect, for if we subtract 1 from 1, the result cannot be anything but 0, and if we subtract 2 from 1, the result must be −1. It is necessary, therefore, to remind ordinary people that if they desire to estimate the number of years from a date in B.C. reckoning to one at the same season in A.D. reckoning, it is not sufficient to add the years together, but unity must be subtracted from the result; from June 1, B.C. 10, for instance, to June 1, A.D. 10, is an interval of not twenty, but only nineteen years.

The author of the work before us desires to prove that those who first used Christian chronology intended that it should be reckoned in this way, the numbers being not cardinal, but ordinal. However, that is a mere matter of curiosity. An inmate of a lunatic asylum, who appeared sane to a visitor, was once asked why he was there. "Oh," he said, "I thought everybody else was mad, and they thought I was; as they were in the majority, they had their way with me, and so I am here."

The majority, in fact, must in all such questions have their way, and the existing system of chronology and its zero point (the end of B.C. 1 or of the year 0 reckoned astronomically) now so extensively pervade all history that they cannot be displaced. As regards the real date of the event on which they are nominally founded, that is another question. It seems clear that Herod the Great died in the spring of 750 by the years of Rome, corresponding to B.C. 4, and that our Lord was probably born towards the end of the preceding year, B.C. 5. Mr. Jordan refers (p. 28) to the proposal to put it back two years further, to A.D. 7, but as that theory is founded on Kepler's suggestion (which cannot be accepted) that the Star of Bethlehem was in fact a conjunction of planets, it may be dismissed as quite untenable. All who have studied mediæval writers on this subject are aware that the original proposal was to date, not from the birth, but from the incarnation of Christ, *i.e.* the Lady Day preceding the nativity; but that was soon merged in the other, which in fact superseded it. We must remind our author that astronomers when making chronological calculations do not call the vulgar era 5 B.C. (for instance) 4 B.C.; they call it A.D. -4, in the ordinary mathematical form when on the other side of the zero point.

It should be added that the book contains some interesting discussions respecting the first use of Christian chronology (superseding the era of Diocletian) and the early cycles used in the determination of Easter. In the application of a cycle there has to be taken into account not only its degree of accuracy (which is only approximate), but the date from which its use has been commenced. It is often forgotten what a twofold operation the Gregorian reformation involved; this, however, was gradually accepted in its entirety in the western church. W. T. L.

TOTEMISM AND EXOGAMY.

Social Origins. By Andrew Lang, M.A., LL.D. *Primal Law.* By J. J. Atkinson. Pp. xviii+311. (London: Longmans, Green and Co., 1903.) Price 10s. 6d. net.

MR. LANG'S critical genius has done great service to anthropology and the science of religion, and the present work, both in its criticism and constructive theory, definitely advances the study of primitive marriage and social organisation.

The essay on "primal law" deals with the origin of exogamy, and may be considered first. Its author, the late Mr. J. J. Atkinson, spent most of his life in New Caledonia, and knew the natives well. His theory, therefore, merits our careful consideration. He takes man in the semi-brutal stage, before language was evolved living, as Darwin thought, not in hordes, but in small unsocial groups, each composed of one adult male with several wives and children. The sons of such a family would be expelled as soon as they reached maturity, owing to the fierce sexual jealousy of the father. This picture is based on what we know, little enough, of man-like apes, such as the gorilla; rightly or wrongly, evidence from cattle and other herding animals is also employed. Such, at least, according to the author, is the genesis of exogamy. He explains the well known avoidance customs between mother and son, brother and sister, as the result of the "primal law," finding a corroboration of his main point in the absence of avoidance between father and daughter. In his account of the further development he is not so successful. The theory, as a whole, is a striking one, and will have to be reckoned with, especially by those who believe in the "horde" as the first form of social organisation, and in communal "marriage" as the original type of union. We are taken so far back in the evolution of man that savage analogies can hardly be applied, and here our difficulties begin. What are the conjugal habits of the higher animals generally, and of the anthropoid apes in particular? Can zoologists give us further evidence beyond the few and possibly doubtful facts hitherto observed on which the theory is based? Another difficulty is the psychological question. We can understand *proprietary* jealousy, and an exclusion of *potential* rivals, both marital and patriarchal; but the sexual instinct of animals in a natural state is as absolutely regulated and free from excess as is that of the normal savage. With regard to the absence of avoidance in the case mentioned above, I am informed by Mr. A. W. Howitt and Prof. Baldwin Spencer that there is no evidence in Australia of such a practice as it would imply. Lastly, one is inclined to suspect single-key theories.

Mr. Lang discusses exogamy, as defined by M'Lennan, and the origin of totemism. With his usual acuteness, he fixes on essential points. In the question of exogamy, an essential phenomenon is the bisection of a tribe, as commonly in Australia, into two exogamous intermarrying moieties, which contain totem-kins; of this a luminous explanation is offered. An exogamous tendency, of whatever origin, is presupposed; then an exogamous local group, which, after the institution of totemism, finds itself composed of variously named units, owing to the presence of alien women, agrees to intermarry solely with another community similarly composed. Such is the origin of the dual phratry system. This explanation is directly opposed to the prevalent view that the bisection was deliberately arranged at a mass meeting of the primitive horde, which had at last discovered the ill effects of promiscuity. But Mr. Lang himself is bound to admit some deliberate grouping of the totems, for we never find the same in both phratries. A final theory might be expected to supply an automatic reason for this result. A more important difficulty, to my mind, is the arrangement of *connubium* between the two local groups; it does not seem clear enough why so many tribes should owe their origin to a *dual* matrimonial alliance.

The explanation of the origin of totemism is suggested by the practice, found in English and French folk-custom, and paralleled elsewhere, of "blazoning" neighbouring villages with sobriquets, which are frequently animal names. The evidence cited on this head is very interesting, and the essential fact has emerged that totem names are *group names given from without.* When accepted, they would be invested

in time, through the action of superstition and myth, with a religious garb, and thus the marriage system would come under their influence. The theory seems to me very nearly, if not quite, to solve the mystery of totemism. There is also some good criticism of recent views, such as the origin of totemism from the "external soul," or from magical cooperative societies for the control of food.

The value of the book is increased by a clear exposition and sane criticism of the chief theories and suggestions which have been put forward in the study of totemism, exogamy, and primitive marriage.

ERNEST CRAWLEY.

OUR BOOK SHELF.

Immune Sera. Haemolysins, Cytotoxins, and Precipitins. By Prof. A. Wassermann, M.D. Translated by Charles Bolduan, M.D. Pp. ix+77. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1904.)

THE subject of immune sera has not in this country received as much attention from the medical profession as its importance and interest deserve. This is not so much due to the inherent difficulties of the subject as to the complicated way in which it has usually been expounded, and to the fact that the nomenclature introduced by different authors and experimenters has been found bewildering. The difficulties have been increased by the introduction by various experimenters of different terms for the same entities, and often ones which suggest the function or properties of the substance, according to the inventor's particular views.

This neglect is the more to be regretted, as investigations upon hæmolysins, cytotoxins, and precipitins which at first seemed to possess merely scientific interest, have become of the greatest importance, owing to the close analogy which has been found to obtain between these phenomena and those of natural and acquired immunity. These studies have indeed occupied an important and striking position in the development of our knowledge of the mechanisms whereby an animal protects itself, or is protected, against the invasion of the micro-organisms of infectious diseases.

This little book of seventy-five pages is an English translation of one of the "Clinical Lecture" series, edited by von Bergman. The treatment of the subject is intended for medical men generally, and is not addressed to specialists. That Prof. Wassermann is the author is sufficient guarantee that the matter has been judiciously selected, and the manner in which it is presented could hardly be improved upon, so that it forms a clear and interesting account of the subject. The main facts and principal conclusions, including a brief but adequate *résumé* of Ehrlich's development of his side-chain theory to apply to anti-bodies in general, are given, but all unnecessary controversial matter is omitted. At the end is a very select bibliography, to which the reader is from time to time referred for fuller information.

The translation is excellent, and we confidently recommend this little book to the attention of all medical men, or others, desirous of acquainting themselves with the essential and most significant facts on the subject of immune sera.

CHARLES J. MARTIN.

The Flora of the Parish of Halifax. By W. B. Crump and C. Crossland. Pp. lxxiv+316. (Halifax Scientific Society, 1904.) Price 10*s*. 6*d*. net.

THE question arises, Why should the records of a parish be amplified into a book containing 300 odd pages? in reply to which the authors explain at the outset that the parish of Halifax covers 129 square miles, and corresponds to a natural geographical division, through which flows the River Calder. But although the area is circumscribed and the vertical range is not great—the altitude varies between 500 and 1500 feet—the number of plants found within the district forms a good list, which has been worked up into an attractive historical and ecological account, and in addition, owing to the cooperation of other workers, it has been possible to include lists of all the cryptogamic plants. Looking at the plant associations, the mixed deciduous woods are the habitat of the globe-flower, the bird's nest orchid, the helleborine and the daffodil, while among the rare species of the heather moors are reckoned the bog-bell, the winter greens, and the bear berry. The bryologist, too, will find a good hunting ground, for, in addition to a fairly rich flora, the parish has yielded a new variety of Philonotis, the first record in Yorkshire for *Amblystegium Juratzkae*, and one of the few stations in the British Isles for *Jubula Hutchinsiae*. With the botany of Halifax is inseparably bound up the name of John Bolton, painter and naturalist, who in 1785 published "Filices Brittanicæ," with thirty-one copper plates all drawn by himself, and in 1791 completed "An History of Fungusses," also provided with plates, and the extent of his collections can be gauged from the numerous records which are given in the book.

While this "Flora" must naturally prove most useful to those who can traverse the parish, the ecological account and the records will serve for guidance and reference to a larger number of naturalists.

Chemisches Praktikum. By Dr. A. Wolfrum. II. Teil. Präparative und Fabrikatorische Übungen. Pp. xii+580. Price 15*s*. net. Atlas, Part ii. Atlas, price 1*l*. net; together, price 1*l*. 8*s*. net. (Leipzig: Engelmann, 1903.)

WE gather from the preface to the first part that the author's intention in compiling this work was to present the student whose aims lie in the direction of chemical technology with a course of practical exercises especially fitted for his future career. The first volume dealt with analytical work, and here the student is introduced to preparative chemistry.

The first chapter is devoted to a discussion of general matters, such as the treatment of materials for preparative and technical purposes, the general conditions of chemical reaction, and the separation, purification, and testing of reaction products. In the second chapter of 150 pages, the methods of preparation of a large number of inorganic and organic substances are described. Fifteen pages form the third chapter, which deals with the dynamics of chemical reactions, and the last two chapters are devoted to matters of a specially technical nature—descriptions of furnaces, autoclaves, filter-presses, air-pumps, condensers, centrifuges, &c., the fitting up of factories, book-keeping, patent laws, and, finally, exercises in connection with large scale technical processes are given.

Such is the programme arranged by the author for the future works chemist. It must be admitted that in many cases the practical courses provided at the universities and higher technical institutions for such chemical students might be with advantage considerably modified; in most cases the chief difficulty confronting such change is to be found in the greatly increased cost of laboratory equipment and upkeep. Without such equipment it is questionable whether the "Chemisches Praktikum" can be advantageously used by the technical student. The preparations are well chosen, but the working details would have been far more intelligible to the average student if

occasionally illustrated by diagrams of the apparatus employed.

What benefit the student will be able to derive from the technical chapters can only be decided by experience. The value of these is undoubtedly enhanced by the supplementary album containing some 560 excellent diagrams illustrating technical apparatus and actual manufacturing processes. Amongst other processes illustrated are the manufacture of liquid ammonia, liquid carbonic acid, chlorine, ether, aniline, hydrochloric, nitric, sulphuric, tartaric, citric, and carbolic acids. A careful study of such diagrams cannot but be of great service to all intending works chemists.

The Personality of the Physician. By Dr. Alfred T. Schofield. Pp. x+317. (London: J. and A. Churchill, 1904.) Price 5*s.* net.

As with all the writings of Dr. Schofield, this present work shows indubitable signs of wide reading and of careful thought.

The underlying gist of the matter is that the most potent factor in a physician's success is the personal equation. Of course, by the word "success" Dr. Schofield does not mean what is sometimes profanely styled "scooping in the shekels"! Nor does he fail into the very common error of confusing *personality* with *prestige.* The latter may, of course, be shared with the physician, who aspires to occupy the most lofty possible pinnacle of moral excellence, by the lowest and most unprincipled charlatan.

Happily, the ethical standard, recognised by the medical profession in this country, is of the highest conceivable type. Nevertheless, any publication that tends to raise, rather than to level down, that ideal is very rightly welcomed alike by the profession, by the Press, and by the people at large.

Some medical men are more comforting than others, and it is quite certain that pessimism more surely empties the consultant's waiting-room than any other quality. If the reviewer, who yields to no man in his admiration of the noblest of all professions, might be for once pardoned for a little private grumble at some of the physicians with whom he has come in contact, it is because of the grudging manner in which certain doctors, otherwise worthy and excellent men, deal out with sparing hand a remedy—Tinctura Spei—which costs them nothing, and yet is probably the most valuable drug ever dispensed!

Rustless Coatings: Corrosion and Electrolysis of Iron and Steel. By M. P. Wood. Pp. x+432. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1904.) Price 17*s.* net.

MR. M. P. WOOD may be a good "practical" man, but he has neither literary ability nor a knowledge of science sufficient to enable him to do justice to a subject which demands much more than rule-of-thumb practice to deal with it adequately. His book is a strange medley of so-called scientific statements strung together without any real acquaintance with their meaning. Its appearance of scientific erudition may serve to deceive the unwary, and we quite agree with Mr. Wood that there is much in paint and in things connected with paint that *is* calculated to deceive the unwary. But then something depends upon the guide. Mr. Wood's book is very prettily got up, and some of the illustrations are in the highest style of process-art. But like much of the subject-matter, many of them are wholly irrelevant. Mr. Wood has evidently had the ambition to make a book on a subject with which as a practical man he has been more or less intimately connected, but in this matter his ambition has overleaped itself.

Ankauf, Einrichtung und Pflege des Motorzweirades. By Wolfgang Vogel. Pp. xiii+144. (Berlin: Phönix-Verlag, 1904.) Price 2.65 marks.

ANYONE who possesses a motor bicycle or tricycle and can read the German language will find in these pages much valuable information in the form of practical suggestions as to the buying, working, and maintenance of these useful means of locomotion. The author deals fully with every part of the machine, and illustrates the text with numerous drawings which should very much assist the novice in understanding the functions of the various parts of the machine. The great improvement in design of motors, and the growing popularity of this form of transport, will no doubt call for many small treatises on the subject, of which the present one is an excellent example.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Origin of Radium.

APROPOS of Mr. Strutt's letter in NATURE of July 7, it may be recalled that the Curies found that the artificially prepared chalcolite (the uranium copper phosphate) contained no radium, whereas the natural substance did.

It appears to me that if this fact is considered along with Mr. Soddy's result as to the failure of uranium nitrate to generate radium, the *prima facie* interpretation would be that the combined copper atom was in some way concerned. Of course the alternative view is still left that it takes a longer time than elapsed in Mr. Soddy's observations for radium to emerge from a succession of changes taking place in the uranium atom, and that this atom is the sole parent. However, in the present state of our knowledge it seems worth investigating if it may not turn out that radium results from the convection of ions from atoms of higher to atoms of lower atomic weight, producing in radium an unstable or overcharged atom.

On these grounds I have recently induced my friend Mr. Emil Werner to prepare about half a kilo. of the uranium mica or chalcolite with the view of testing at intervals its yield of radium emanation, if any is, indeed, generated. Along with this will be observed the pure uranium nitrate as well as an impure uranium nitrate recrystallised with small quantities of some of the heavy metals. My experiments are on rather a small scale. It is desirable, I think, that they should be repeated by some one commanding larger resources.

J. JOLY.

Trinity College, Dublin.

Electric Wave Recorder for Strutt's Radium Electroscope.

THE periodical discharges of a Strutt's radium electroscope can be arranged to ring a bell or print a record of every contact of the leaves; each discharge from the outside terminal, when the leaf strikes, is sufficient to act on a coherer, if any part of the coherer circuit is connected by wire, so that the discharge terminal of the vacuum tube takes the place of the aërial, as used in wireless telegraphy; the experiment never fails, every discharge producing a ring on the bell or a dot on the Morse tape as desired. For the coherer I use two pieces of No. 16 German silver wire, with nickel filings in the gap, at ordinary atmospheric pressure.

It is sometimes possible to get the coherer to respond by induction without metallic contact with the terminal, but this is rather beyond the sensibility of the apparatus employed.

I am greatly indebted to Dr. W. H. Martindale for the loan of his Strutt's radium electroscope for use in these

experiments; the performance of this instrument is very fine; the quantity of radium enclosed is nearly 3 milligrams; this produces a discharge at intervals of about 70 seconds—this rate is not in any way altered by attaching the coherer and apparatus. F. HARRISON GLEW.

156 Clapham Road, S.W., July 1.

THE MEMORIAL TO SIR GEORGE STOKES.

ON Thursday last, July 7, the memorial to Sir George Gabriel Stokes was unveiled in Westminster Abbey by the Duke of Devonshire in his capacity of Chancellor of the University of Cambridge.

The initial steps for the erection of this memorial were taken at a joint meeting of representatives of the Royal Society and the University of Cambridge, held in the Royal Society's rooms on March 12, 1903, when a committee was constituted to devise measures for providing a public memorial to commemorate the scientific career of Sir George Stokes and to take steps for carrying the project into effect. On that occasion it was decided to send a letter, in the names of the Chancellor of the University of Cambridge and the president of the Royal Society, requesting the authority of the Dean and Chapter of Westminster to place a memorial in the Abbey in the form of a medallion relief portrait of Sir George Gabriel Stokes, of the same general character as the memorials of Charles Darwin and other scientific men now in the Abbey. At the same time a subcommittee was formed to collect subscriptions for the purpose in view, and for carrying out the resolution of the full committee. In response to the committee's application the Dean gave his assent to the proposal, and agreed to take detailed plans into consideration. The subcommittee consequently, in consultation with the Dean, offered a commission to Mr. Hamo Thorneycroft, R.A., to execute a medallion.

The ceremony on Thursday was preceded by a meeting, in the Jerusalem Chamber, of subscribers to the memorial, and personal friends of Sir George Stokes. The meeting was presided over by the Dean, and was attended by many distinguished men of science and of letters. The Dean was supported by the Duke of Devonshire, Sir William Huggins, president of the Royal Society, Lord Kelvin, Lord Rayleigh, Prof. Larmor, and Prof. Forsyth (honorary secretaries to the memorial fund), and Mr. Kempe, treasurer of the Royal Society. There were present also the American Ambassador, Mr. Bryce, Sir William Crookes, Prof. George Darwin, Sir James Dewar, Sir Joseph Fayrer, Principal Carey Foster, Mr. Francis Galton, Sir John Gorst, Prof. Liveing, Sir Norman Lockyer, Sir Andrew Noble, Dr. Thorpe, and many other fellows of the Royal Society.

Prof. Larmor read letters from the Prime Minister, Lord Lister, Sir Joseph Hooker, Sir Michael Foster, Lord Goschen, Lord Avebury, and others expressing regret for their unavoidable absence.

The Dean opened the proceedings, and prefaced his remarks by directing attention to the increasing difficulty of finding space within the Abbey for such memorials as that which they were met to dedicate. He stated the history of the movement described above, and referred to the wonderful trio of famous senior wranglers occurring in successive years, Stokes, Cayley, and Adams, followed two years later by Lord Kelvin, and enlarged upon Stokes's lofty personal character, his peculiar greatness of mind, his generosity, and his humility. The Dean regretted the impracticability of devising a motto for the memorial tablet which could with sufficient terseness express the comprehensive range of Stokes's genius.

The Dean then called upon Sir William Huggins, president of the Royal Society, who, after referring to the part the Royal Society had taken in the movement for the memorial, spoke of the great services rendered to the Royal Society by Sir George Stokes during his thirty-one years' tenure of the secretaryship of the Society and his subsequent five years' occupancy of the presidential chair. Sir William referred to the wide range of Stokes's discoveries and particularly to the great advances which he made in the application of mathematics to physics. He extolled the wonderfully even balance of his powers and his remarkable soundness of judgment, and contended that his influence on his time was due as much to his greatness of character as to his intellectual accomplishments. He therefore held him worthy of a shrine by the side of Newton, Herschel, Darwin, Adams, and Joule.

Lord Kelvin described in some detail, and eulogised the great range and broad aspect of Stokes's work in science, and pointed out how fruitful it had been of great developments in recent times. He referred to his investigations upon elasticity, his paper of 1850 upon water waves, his researches in light and optics, and particularly to his discovery of fluorescence; and reminded his hearers that Stokes's work and thought are but partially represented by his published writings. He recalled the indebtedness of many authors of scientific papers to Stokes for aid and illumination received from him during his long secretaryship of the Royal Society, and in feeling terms referred to his own relations with Stokes, saying, "For sixty years of my own life I looked upon Stokes as my teacher, guide, and friend. His death was for me truly a bereavement."

Lord Rayleigh, speaking as a pupil of Sir George Stokes, described his experiences as a student at his lectures, and the unbounded admiration he always felt for him as a teacher, a man, and an investigator. He held up as an example still to be followed the simplicity of Stokes's experimental methods and his limitation of his apparatus to the bare essentials for the demonstration of the principles he was expounding. Lord Rayleigh referred more particularly to some experiments and investigations of Stokes, including those on the spectrum of the blood, on the theory of spectrum analysis, and to some of his incidental papers on acoustics, and said that Stokes's papers, whether mathematical or physical, or both, were always interesting to read.

The Vice-Chancellor of the University of Cambridge, speaking on behalf of the University, welcomed the honour done to Stokes's memory by this memorial. He paid an eloquent tribute to his great character, to his loyalty and affection for his university and college, and said that the university rejoiced that his name would now have a permanent memorial on the historic walls of that great national church.

The company then proceeded to the Abbey, where, after a prayer from the Dean, the Duke of Devonshire removed the cover from the medallion, which hangs on the wall with those of Adams and Darwin in the north aisle of the choir of the Abbey.

The Duke of Devonshire said, "Speaking on behalf of the subscribers, I offer this medallion to be added to the memorials and to be preserved in the Abbey church."

The Dean responded, "Speaking in the name of the Dean and Chapter of Westminster, I accept this medallion to keep and preserve among the memorials of the good and great men in this place."

The memorial is in the form of a bronze medallion, with a portrait head of Sir George Stokes in very high relief, and bears the inscription, "George Gabriel Stokes, 1819–1903."

A STORY OF THE PHILIPPINES.[1]

MOST people, after reading the latest work of that indefatigable traveller Mr. Savage Landor, will be disposed to question the appropriateness of his title "Gems of the East." Beyond the attraction of remoteness (which always possesses a fascination for the explorer), and the interest which still lingers round the records of the American occupation of those islands, there does not appear to be much in the humid, swamp-ridden plains, or in the volcanic hills of the Philippines to justify the suggestion of entrancing glitter and brightness; even if it justifies the production of two volumes of statistical detail about them.

FIG. 1.—Woman carrying Water in a Bamboo Cylinder. From "Gems of the East."

In some respects this latest of Mr. Landor's works differs essentially from its predecessors. There is far less effort to maintain the interest of the reader by a narrative of perilous adventures and hairbreadth escapes, and much more appeal to the student of science generally, and of anthropology in particular in which branch, indeed, Mr. Landor shows himself to be an expert. So far, perhaps, the author is to be congratulated, for there must certainly be amongst his assortment of observations on subjects geological, botanical and ethnographical, or purely anthropological, many which are new to science, and therefore valuable. Nor are the incidents of adventure by any means wanting. There is room in the book for new records of perils by land and sea—adventurous rock-climbing, rough and ready campaigning with American troops, coast exploration, collisions with cannibals and head hunters, &c.—which recall the exploits of the Savage Landor of Tibet and Baluchistan; but they are no longer the mainstay and objective of the work.

The present book contains far more of patient and honest scientific research than of those fantastic performances as an explorer which have made Mr. Landor famous. His manner of writing is familiar and colloquial, occasionally almost ungrammatical. Taking the reader by the arm (metaphorically, for he is careful to explain that he always travels alone), he leads him gently to the outermost verge of civilised existence, and there introduces him to a race of people scattered in innumerable tribes through the islands of the Philippine group, who are so little understood, even by their American administrators, as to be amongst the most interesting of those aborigines of humanity who are still left struggling against the world-swamping waves of civilisation. They will doubtless "go under"—absorbed by the spread of those growing and expanding nations who will finally reduce the ethnographical conditions of the world to one dead level of uninteresting development. Judging from Mr. Landor's description of the countries which they occupy, and of the advance of American institutions amongst them, it will probably be long yet ere the Philippines assume a social condition analogous to that of Cape Colony or of India; but the process is none the less sure because it is slow. Mr. Landor is naturally charmed with the Americans whom he met in the Philippines, and some of the best chapters in his book are those which recount the familiar story of administrative difficulties and of tribal resistance,

FIG. 2.—Bontoc Igorrotes: showing resemblance to Ainu of North Japan. From "Gems of the East."

drifting finally into armed expeditions and the reduction of native strongholds.

American pluck and endurance are fully tested in these little frontier wars, which afford opportunities for the practical training of soldiers such as are rapidly disappearing on the borderland of the continental Red Indian. Cholera appears to be their deadliest foe in the field, allied to certain forms of local disease the exact nature of which is not readily recognisable from Mr. Landor's description. The author has no high opinion of modern medical science. The Filipinos (he tells us) are not yet foolish enough to believe in the mosquito theory for malaria. Nevertheless, they build their houses on piles so as to raise them sufficiently above the humid atmosphere of the ground level to ensure a free current of air. Nor does he himself believe in the efficacy of boiling water in order to render it free from germs and choleraic impurities. Precautions of any sort, indeed, do not appeal to his spirit of chivalrous adventure. When climbing precipices "I did not use ropes or other such nonsensical Alpinistic devices; my rule has always been to use common sense and avoid all accidents." This certainly is an excellent rule (if not entirely original), and one much to be commended to the Alpine Club. But combined with a proud disregard for such conventional appliances and precautions as usually become more valued by the geographical explorer the farther his experiences extend, Mr. Landor undoubtedly possesses that great faculty of human sympathy which enables him to deal with all classes of people, and to obtain the confidence (even the cooperation) of the aboriginal natives in branches of research which must have appeared to them exceedingly strange and suspicious. It is most difficult to persuade the brawny independent savage of the jungle to permit himself to be handled and measured, to have calipers applied to his head, and a minute examination made of all the features which nature has given him, for a purpose which is absolutely unintelligible to his limited understanding.

But Mr. Landor succeeded admirably, and the result is undoubtedly a valuable contribution to anthropological science, although the constant repetition of tables of measurement might very well have been dispensed with in a book which (regarded as a popular work) is already too long.

The multitude of the islands forming the Philippine group, and the excessive variety of detail which permeates them, the differentiation between the many tribes which inhabit them, and even the enumeration of their extraordinarily abundant vegetable products, become confusing after a while, and it is a relief to turn to the story of pure adventure, and the occasional interludes of graphic description, which is what the world looks for from Mr. Landor's pen. Doubtless it is Mr. Landor's intention to pose seriously as a scientific observer, and there is quite enough in the book to justify the assumption; but it might have been better had he made a little wider separation between that which belongs to the realm of statistical detail and that which is narrative of personal adventure.

T. H. H.

A PROBABLE CAUSE OF THE YEARLY VARIATION OF MAGNETIC STORMS AND AURORÆ.

IN a previous number of this Journal (vol. lxvii. p. 377) an account was given of the very close relationship which seemed to exist between the epochs of the occurrence of prominences in the polar regions of the sun and Ellis's "great" magnetic disturbances. In a later number (vol. lxviii. p. 257) it was shown that the presence of these polar prominences synchronised also with the appearances of large "polar" coronal streamers as seen during total solar eclipses. Disturbances near the solar poles seemed to play such an important *rôle* both in solar and terrestrial changes that an inquiry was made to find out whether any effect is felt on the earth when either of these solar poles is turned towards the earth during the course of the year. The result of such an investigation, recently communicated by Sir Norman Lockyer and the writer to the Royal Society, will here be briefly stated.

During the course of a year the south pole of the sun is most turned towards the earth in the beginning of March, and the north pole most towards the earth in the beginning of September. At the two intermediate epochs, in the beginning of June and December, neither pole is turned towards or away from the earth, but occupies an intermediate position. Hence we see that the *equinoxes* occur in the same

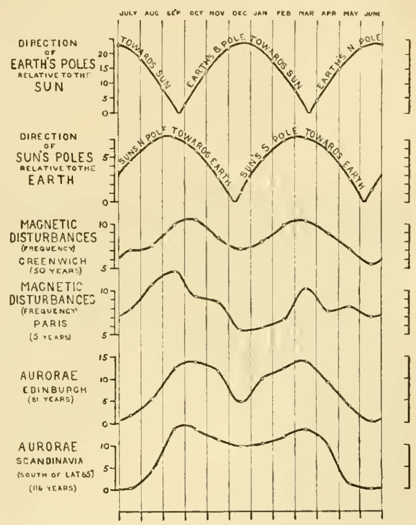

FIG. 1.—Curves showing the relationship between the positions of the earth's poles in relation to the sun, the sun's poles with regard to the earth, and the frequency of magnetic disturbances and auroræ throughout a year.

months as those in which one or other of the solar poles is turned towards the earth, while the neutral positions of the solar poles in relation to the earth occur in the same months as the *solstices*.

If, therefore, these solar polar regions are capable of disturbing the magnetic and electric conditions on the earth, then, when they are most directed to her at the equinoxes, the greatest effects during a year should be recorded, and when they are least directed the effects should be at a minimum.

With regard to the facts about the variation of magnetic disturbances and auroræ, Mr. Ellis has shown that the curves of frequency of magnetic disturbances at Greenwich and Paris are very similar, "showing maxima at or near the equinoxes, and minima at or near the solstices." These also, he further points out, are similar, with regard to the epochs of maxima, to the curve representing the

frequency of the aurora at London. In the case of auroræ observed in Edinburgh, north-east Scotland and in different regions in Scandinavia, the months in which the greatest frequency is recorded are September and October (perhaps more generally October) and March and April (perhaps more generally March).

The accompanying figure (Fig. 1) shows in a graphical form the annual variation of these magnetic and auroral frequencies, indicating their epochs of maxima and minima. Above them are the curves showing (at the top) the epochs when the *earth's poles* are turned towards the sun (the origin of our seasonal changes) and (below) when the *sun's poles* are turned towards the earth.

The coincidence in time between the epochs of the maxima of the frequency of magnetic disturbances and auroræ, and those of the greatest inclination towards the earth of the north and south solar polar regions can thus be seen at a glance.

The inquiry was pursued further to find out whether this yearly inequality of these terrestrial magnetic disturbances was influenced differently according as the sun's polar regions were, for several groups of years, in an undisturbed or disturbed condition.

It was expected that the oscillation of more disturbed solar polar regions towards and away from the earth would tend to *increase the difference* between the frequency of magnetic disturbance at the equinoxes and solstices, while this difference for those years when the less disturbed solar polar regions were in action should be somewhat *reduced*.

It was shown in the paper that this is actually the case, the frequency of the magnetic disturbances at the equinoxes being in greater excess over the solstitial frequency the greater the degree of disturbance.

There is thus reason to believe that the orientation of the solar poles with regard to the earth is the origin of these magnetic and electric annual changes.

WILLIAM J. S. LOCKYER.

THE ORNITHOLOGIST IN LAPLAND.[1]

RUSSIAN Lapland, although it has its charms during the brief summer, cannot be described as a desirable country, either for residents or tourists, since, except in a few sheltered spots, it produces little fodder save reindeer moss, while the fishing and shooting are but indifferent, and in late seasons the ground may remain covered with snow until well into June. Moreover, almost as soon as summer has set in, mosquitoes of a particularly vicious kind make their appearance in swarms, and render life well-nigh intolerable in the marshy districts which form the greater part of the country. When to these drawbacks are added the difficulties of travel, both by sea and land, there is little wonder that northern Lapland attracts

FIG. 1.—Driftwood on Beach, Kanin. From Pearson's "Three Summers among the Birds of Russian Lapland."

[1] "Three Summers among the Birds of Russian Lapland." By H. J. Pearson. Pp. xvi+216; illustrated. (London: R. H. Porter, 1904. Price 21s. net.

but few tourists. Nevertheless, to the ornithologist and the egg-collector it is little short of a paradise, birds of many kinds resorting to its inhospitable shores for the breeding season in vast numbers. The variety and abundance of bird-life are, indeed, testified by the statement of the author of the handsome and exquisitely illustrated volume before us, that during his first trip he encountered no less than seventy-six species, of forty-four of which he succeeded in obtaining the eggs. This exuberance of bird life the natives do their best to keep in check, and it must be confessed that a bird protection society would find plenty of scope in the country, as all birds large enough to be eaten are shot during the breeding season, while the eggs of many species are taken by the thousand. An excuse for these practices is to be found, as the author states, in the circumstance that birds only visit this part of Lapland in order to breed, and if they did not do so then, the natives would never have a chance of killing them at all. Loons, or divers, it appears, are often taken accidentally in fishing nets, but puffins, which swarm in the country and have been described in an official publication as "ducks," are taken for food by stretching old nets across their holes.

Previous to the first of the three trips recorded in this volume, Mr. Pearson had already visited Lapland, and has described his experiences in "Beyond Petsora Eastward." Of the three trips described in the present work, the first was undertaken in 1899, and was devoted to the exploration of the northern districts of the country; in 1901 the author visited the Kanin Peninsula, while in 1903 he penetrated the interior of the country south of Kola. The year 1899 was remarkable for the late melting of the snow, which still covered the country on June 2, when the herring-gull was found nesting on little patches of clear ground in the snow. During this year the starling seems to have first extended its range into the country, the species being at that time quite unknown to the natives. Among the larger birds, white-tailed eagles were found to be not uncommon, although, owing to the rewards offered by Government for their eggs and young, they can only build in safety on inaccessible crags. Ospreys were, however, sought in vain, these birds being persecuted by the Finns on account of the fish they destroy. An immense eagle's nest in one of the few trees remaining on the Murman coast was one of the "finds" of this trip. Very notable, also, was the discovery of a nest of the rough-legged buzzard on the ground. Among the prizes in the way of eggs may be mentioned those of the little stint and the dotterel, while those of the turnstone, although by no means uncommon, were exceedingly difficult to discover. A breeding colony of glaucous gulls yielded quite a harvest of eggs. Apparently the earliest breeder is the Siberian jay, which nests in April, when the country is inaccessible, except on ski. During his trip the author was fortunate enough to come across an old Finn who collected with John Wolley forty years ago on the Gulf of Bothnia.

The accompanying picture is an example of the illustrations which render this interesting and well written volume so attractive. R. L.

PROF. CHARLES SORET.

CHARLES SORET, honorary professor of physics at the University of Geneva, whose recent death we regret to announce, was born at Geneva on September 23, 1854. After a general course of study at the college and at the university of his native town, he devoted himself especially to the study of physics. In this he followed a family tradition, his father being the Genevese physicist Jacques-Louis Soret. Like his father, from whom he inherited his deep love and respect for scientific truth and his scrupulously exact method of working, he will be remembered as one of the most distinguished representatives of the science of Geneva. During many years, until the death of Louis Soret in 1890, he was his father's colleague and collaborator.

Charles Soret took successively at Paris the degrees of licentiate in physical science in 1876 and of licentiate in mathematical science in 1878. After a visit to Germany he returned in 1879 to the University of Geneva to fill the chair of mineralogy, a subject which, by the enthusiasm of his teaching, he rendered widely popular. His earliest works date from this period; they are published in the *Archives des Sciences physiques et naturelles* of Geneva, a journal with which he was associated during more than twenty years, and to the publication committee of which he rendered many signal services. Little noticed at first, the works of Soret opened out the way for other investigators; at the present day every mineralogist is acquainted with "Soret's Law" and "Soret's refractometer." Crystallography was the science especially cultivated by Soret; the subject-matter of his course was published by him in 1893, under the title of "Éléments de Cristallographie physique," a work well known and appreciated by specialists.

On Wartmann's death in 1886, Soret was called to the chair of experimental physics in the University of Geneva, and during two years he was burdened with a double duty. By transferring the mineralogy course to one of his students, he was enabled to continue his own peculiar studies, especially in the domain of crystallographic optics, for which he showed a marked preference. He was an excellent professor of physics and gave a new impulse to the study of that science at Geneva; the laboratory was largely extended, and many serious students came to group themselves around a master so conscientious as to devote himself almost exclusively to their scientific training. Soret would certainly have published more had he not given himself with so single a mind to the exacting and fatiguing duties of directing his laboratory.

A valued member of the faculty of science, he was at the same time appreciated by the whole university. After serving during a long period as secretary of the university senate, he was, in 1898, appointed to the honourable but exacting office of rector of the university. Owing to his serious qualities, to his firm but conciliatory character, he wielded great authority, and his duties as rector were filled with rare distinction. Applying scientific method in all things, he was a remarkable administrator, and many are the services he rendered to the university. But he overtaxed his powers, and when his rectorate expired, in 1900, he was forced to resign his professorship, a step which caused profound regret among his colleagues and friends.

After a rest of two years his health seemed re-established. He resumed his scientific activity and his researches in the laboratory that he had created. He had just published in the *Archives* for March, 1904,[1] a new investigation of the refraction of tourmaline when, on April 4, he was removed from his family and friends by a sudden illness.

The death of Soret is a great loss to his country and to science in general. Much might still have been anticipated from a mind so lucid, so methodical,

[1] The completion of this work is published in the May number of the *Archives*.

and so truly scientific. In spite of his modesty, his great natural abilities made him famous in Geneva, in Switzerland, and abroad. His death leaves a gap difficult to fill. R. Gautier.

PROF. THEODOR BREDICHIN.

For the past ten years Prof. Bredichin lived in well-earned and dignified retirement in Saint Petersburg. After a life spent in directing, with consummate ability, the activities of the two great astronomical observatories of Moscow and Pulkova, he sought, while his energies were still vigorous, opportunity for cultivating with greater leisure those studies to which he had conspicuously devoted himself while in a public position. In the midst of that self-imposed work and at the zenith of his reputation, he has been removed by death to the profound loss of science in Russia. In 1857, he was called to fill the chair of astronomy in the University of Moscow, and with it to undertake the direction of the observatory. There he remained for thirty-three years, and devoted himself to astrospectroscopic observation, a subject new in Russia, to the study of variable stars, to gravity determinations by means of pendulum observations, and to a host of inquiries with which his name has long been connected. But most of all was his attention concentrated upon the formation and behaviour of comet tails, a subject which had practically lain dormant since Bessel's researches on the comet of Halley. Of this subject he never wearied, and shortly before his death he collected and published his more important papers bearing on this inquiry. This revision was perhaps the more necessary since photographs had revealed minuter details than could easily be detected in the ordinary telescope. It must be a matter of gratification to his numerous friends that the distinguished astronomer, in spite of bad health, was able to complete a task which had occupied him for so many years.

In 1890, when Prof. Otto Struve retired from the direction of the Pulkova Observatory, Dr. Bredichin took charge of that institution, but his health did not permit him to remain long at this post, and in 1894, accompanied by the regrets of the staff, he resigned his position at the observatory, but not before he had given a decided impetus to the progress of celestial photography. We have already intimated how, in the remaining years of his life, he sought to promote the interests of his favourite science.

Some 150 papers on a variety of subjects were published by Dr. Bredichin, and by the foundation of prizes for special astronomical inquiries he still further encouraged the science. As a teacher he enjoyed the reputation of being able to inspire his pupils with a lifelong interest in astronomy, and the present position of the science in Russia owes not a little to the enthusiasm which he imparted to his pupils. At the age of 73, but with his faculties acute and with his interest in astronomy unimpaired, Russia has to regret the loss of one of her most brilliant sons, while science is deprived of an ardent and enthusiastic supporter.

ROYAL COLLEGE OF SCIENCE, 1903.

Science scholars selected from the whole of Great Britain for their ability and promise, maintaining themselves on 17s. 9d. a week, were this year saved from much privation by secret gifts of small bursaries—see the subjoined audited account. Prof. Perry says he has no right to ask for help from the generous men who helped him last year, but he has all the sturdiness of a chartered beggar—he asks in a good cause.

Royal College of Science.

BALANCE SHEET.

BURSARIES 1903–1904.

Moneys Received and Paid by Prof. Perry, November, 1903, and June, 1904.

Received		Paid	
Balance in hand from last year	£31 5 0	*Nov.* 16 *to April* 25. 27 students received half-bursaries ...	£135 0 0
September, 1903.		*March* 23.	
R. K. Gray, Esq....	10 0 0	1 student received the second half ...	5 0 0
B. Hopkinson, Esq.	10 0 0	*June* 10 *to June* 14.	
Sir A. Noble, K.C.B.	10 0 0	23 students received the second halves of their bursaries...	115 0 0
October 8, 1903.		Balance in hand ..	24 2 0
W. F. Stanley, Esq.	10 0 0		
The Drapers' Co....	100 0 0		
The Goldsmiths' Co.	100 0 0		
(*Royalties.*)			
Prof. Perry	5 7 0		
Paid back ,.. ...	2 10 0		
	£279 2 0		£279 2 0

Twenty-seven students received 5*l.* each; only twenty-four of them applied for the second halves of their bursaries.

Audited and Signed by John W. Judd.

Dated June 23, 1904.

NOTES.

An important deputation organised by the British Association will be received by Mr. Balfour to-morrow (Friday) afternoon, and will support the plea for the State endowment of higher education and research presented by Sir Norman Lockyer in his presidential address last year. Oxford and Cambridge will be represented by their Vice-Chancellors and others, London University by Lord Rosebery (Chancellor) and others, and the Birmingham University representatives will be headed by Mr. Chamberlain (Chancellor), who it is hoped will speak for all the new universities. According to a statement prepared by the president of the British Association and revised by a committee consisting of the Deputy Vice-Chancellor of Oxford, the Vice-Chancellor of Cambridge, Sir Oliver Lodge, principal of Birmingham University, Sir Michael Foster, M.P., and Sir Henry Roscoe, the British Association has taken action regarding the State endowment of universities, because at the present juncture the highest education and research is a matter not merely of academic, but of the gravest national concern.

Prof. G. Gaffky, professor of hygiene in the University of Giessen, has accepted Prof. Koch's vacant chair in the University of Berlin.

The following appointments are announced in connection with the Institut Marey:—Prof. A. Chauveau has been elected president and director; Prof. H. Kronecker becomes vice-President; Prof. M. Levy, treasurer; and Prof. G. Weiss, secretary.

The sixth centenary of the birth of Francesco Petrarca will be celebrated at Arezzo from July 20 to 25. Among the festivities will be an historic *fête* in the amphitheatre of the Prato in fourteenth century costume, commemorating the arrival of Petrarca at Arezzo in 1350.

The Mackinnon studentships of the Royal Society have been filled for the ensuing year by the election of Mr. Bryan Cookson for research in astronomy, and particularly for a new determination of the constant of aberration and

for an investigation of the mass and compression of Jupiter and of corrections to the elements of the orbits of his satellites; and to Mr. L. Doncaster for research on the early development of the egg, &c., in various species of sawflies, and for breeding experiments with certain species of Lepidoptera and with domestic animals.

A COMMITTEE has been formed in the Victoria University of Manchester to procure a portrait of Prof. Osborne Reynolds, F.R.S., the senior member of the teaching staff, as a memorial of the long and distinguished services which he has rendered to the Owens College and of his many valuable original contributions to physical science and engineering. In view of the eminent and widely recognised position which Prof. Reynolds holds as a scientific investigator, it is felt that there are many friends not immediately connected with the university who would be glad to be associated with the memorial. Any subscriptions should be sent to the treasurer of the Manchester Committee (Mr. S. Chaffers, Owens College).

SIR OLIVER LODGE, and other representatives of leading educational institutions in Birmingham, have addressed a memorial to the Lord Mayor of the city suggesting the establishment of a natural history museum on a portion of land recently acquired by the corporation. The memorial states:—"The absence of such a museum is, in our opinion, a grave defect in our municipal institutions, and is a matter of astonishment to strangers visiting our city. Several valuable collections of objects of natural history have already been lost to the city for want of a suitable building in which to deposit them, and many more collections—zoological, entomological, botanical, and geological—will find their way to metropolitan and other museums if suitable provision is not made in Birmingham for their reception."

IT is proposed to hold an optical convention in London next year. At a meeting held on Monday, in the rooms of the Society of Arts, Dr. R. T. Glazebrook, F.R.S., the president of the Optical Society, occupying the chair, an executive committee was elected, and the following were elected honorary vice-presidents:—Lord Crawford, Lord Rosse, Lord Rayleigh, Lord Blythswood, Sir William Abney, the Hon. Alban Gibbs, Mr. W. H. M. Christie (the Astronomer Royal), Mr. T. R. Dallmeyer, Mr. J. Stuart, Sir Howard Grubb, Dr. Glazebrook, and Lord Kelvin. One of the honorary vice-presidents will be asked to take the position of president of the convention.

THE report of the committee on ancient earthworks and fortified enclosures was presented to the congress of archæological societies on July 6. The committee expresses regret that more archæological societies have not taken up the idea of compiling a schedule of the ancient defensive works in their respective districts; and it is urged upon the secretaries of societies to arrange, when possible, for the survey and scheduling of all such works as are included in the inquiry. The committee concludes the report by again impressing upon archæologists the importance of doing their utmost to prevent the destruction which from time to time threatens so many defensive enclosures of earth or stone.

THE seventy-second annual meeting of the British Medical Association will be held at Oxford from July 26–29. The president is Dr. T. D. Griffiths, and the president-elect Dr. W. Collier. An address in medicine will be delivered by Sir William S. Church, Bart., K.C.B., and an address in surgery will be delivered by Sir William Macewen. A popular lecture will be delivered by Dr. G. Bagot Ferguson on Thursday evening, July 28. The annual meeting this year will comprise fourteen sections, which, with their presidents, are as follows:—Medicine, Dr. W. T. Brooks; Surgery, Mr. H. P. Symonds; Obstetrics and Gynæcology, Dr. F. H. Champneys; State Medicine, Dr. J. S. Haldane, F.R.S.; Psychological Medicine, Dr. C. A. Mercier; Pathology, Dr. J. Ritchie; Physiology, Prof. Francis Gotch, F.R.S.; Anatomy, Prof. Arthur Thomson; Ophthalmology, Mr. R. W. Doyne; Dermatology, Dr. T. C. Fox; Laryngology and Otology, Mr. C. J. Symonds; Tropical Diseases, Dr. A. Crombie, C.B.; Navy, Army, and Ambulance, Surgeon-General A. Frederick Bradshaw, C.B.; Dental Surgery, Mr. E. A. Bevers.

THE third annual meeting of the general committee of the Cancer Research Fund was held last Friday, July 8, at Marlborough House, the Prince of Wales occupying the chair. The report of the superintendent (Dr. Bashford) details the work that has been carried out during the past year. Specimens of new growths have been examined from a variety of animals, including fish and a wild mouse, showing that cancer occurs in animals in a wild state. Certain cells of malignant new growths have been found to present nuclear changes similar to those by which the sexual cells are prepared for fertilisation, and the fusion of nuclei has been demonstrated in tumours of the mouse. These observations suggest that the new growth of cancer is a mass of cells that has taken on an independent existence. Statistical investigations have also been carried out, and among other things do not support the widely spread belief that cancer is on the increase. The report of the treasurer appeals strongly for more extended pecuniary support; out of a population of 40 millions only 328 individuals and 10 city guilds have contributed, and the income has proved insufficient to meet current expenses.

ON Monday a large deputation waited on Lord Londonderry, President of the Board of Education, to urge the compulsory teaching of hygiene in elementary and secondary schools. The deputation was in support of a petition which has been signed by nearly fifteen thousand medical practitioners. The petitioners urged the central educational authorities of the United Kingdom to consider "whether it would not be possible to include in the curricula of the public elementary schools, and to encourage in the secondary schools, such teaching as may, without developing any tendency to dwell on what is unwholesome, lead all the children to appreciate at their true value healthful bodily conditions as regards cleanliness, pure air, food, drink, &c." The petitioners remark that a widespread ignorance prevails concerning not only the nature and properties of alcohol, but also its effects on the body and the mind. Central education authorities are therefore asked to include in the simple hygienic teaching desired elementary instruction at an early age on the nature and effects of alcohol. Dr. Farquharson, M.P., introduced the deputation, and short speeches in support of its objects were made by Sir W. Broadbent, Dr. D. Griffiths, Sir T. Barlow, Sir Lauder Brunton, Sir Victor Horsley, Dr. Mary Scharlieb, Dr. Hutchinson, and Prof. Sims Woodhead. Lord Londonderry, in reply, said the proposals made by the deputation had his sincerest sympathy, and he only wished it was in the power of the Board of Education to carry them out. He was as anxious as anyone to see increased instruction being given in the laws of health, but at the present time the necessary teachers did not exist, and he should be the last to wish anybody to act as instructor in such important subjects who had not received instruction in them. The Board was at the present moment

devoting itself to the training of teachers and instructing them properly in the whole question of hygiene. He trusted that as time went on its efforts in that direction would bring about the desired results.

In forwarding to Sir C. Eliot the meteorological returns from fourteen stations in British East Africa, for 1903, Dr. Johnson gives some particulars about the rainfall, and these have been forwarded to us by the secretary of the Meteorological Office. The average amount of rain did not fall in the coast region during the period covered by the report, only 33.84 inches being recorded at Mombasa, 23.24 inches at Malindi, 35.18 inches at Rabai, and Takaungu received 33.72 inches. Shimoni fared better in this respect, as 42.51 inches fell at that station. At up country districts the amount of rain was well up to the average; 80 inches fell at Mumias, 60 at Kisumu, and 51 at Fort Hall. The number of rainy days, *i.e.* days on which at least 0.01 inch of rain fell, varied from 23 at Kismayu to 174 at Eldoma; and at Machakos the number was 93; at Fort Hall, 110; at Nairobi, 111; at Kisumu, 127; and at Mumiàs, 145. The greatest amount of rain which fell in one day was 5.61 inches at Machakos, on April 28, and the next heaviest rainfall was 4.77 inches at Nairobi, on April 27. The Egyptian Survey Department having asked for returns relating to the lake levels, and also for returns of rainfall from places where the amount of water in the lake would be affected by the amount of rainfall, Dr. Johnson has forwarded instruments to the stations in question, viz.:—Nandi, Kericho, and Karungu. A supply of instruments has also been sent to Morendat and to Nairobi, and it is hoped shortly to supplement those already at Fort Hall.

In *Symons's Meteorological Magazine* for June there is a description of a new pattern rain gauge by Messrs. Lander and Smith, of Canterbury, a firm of chemists which has also recently produced some ingenious self-recording instruments. The chief novelty is that the glass receiver is permanently fixed to the funnel, and by means of a tube the contents can be emptied for measurement into an ordinary measuring glass. The latter is conical below, so that the graduation of small quantities of rainfall may be more accurately measured than is the case in an ordinary glass. A somewhat similar arrangement was proposed by Mr. John Aitken, F.R.S., in the same magazine in 1902, and Dr. Mill then pointed out that in Prof. Hellmann's rain gauges, used at official stations in Germany, the measuring glasses are constructed on the principle suggested by Mr. Aitken, the graduation of the first 10mm. being fifteen times as long as the others. The "Camden" rain glass recently designed by Messrs. Negretti and Zambra is also conical at the lower end. This arrangement enables the observer to decide, without guessing, whether in cases of very slight rainfall the amount is nearer 0.01 inch than 0.00, and consequently whether the day should be counted as a "rain-day" or whether the precipitation should be disregarded.

A new self-recording mercurial barometer has been devised by Mr. W. H. Dines, and is a much improved form of the instrument known as Milne's barograph. Its basis is, therefore, a glass syphon mercurial barometer, having its shorter limb, and a length of the upper portion of its longer limb, of considerably wider calibre than the remainder of the tube. In the shorter limb of the Dines pattern of the instrument, an iron float, of peculiar construction, moves freely, and through the medium of flexible lines connected to the arched heads of a lever-beam (or differential pulley) multiplication arrangement, this float actuates the recording pen. The clock movement is of Richard's type, and is enclosed within a long but light ebonite cylinder, which it drives, and on the outside of which is wrapped the chart (all the divisions on which are rectangular). The principal feature of Mr. Dines's new pattern of the instrument is a neat temperature-compensating arrangement embraced in the float. The iron float is essentially a cylinder, sealed and weighted at the top, but open underneath, below the level of the mercury in the short limb of the syphon, and when in position the cylinder contains air. It will be evident upon consideration that, given a suitable amount of air within such a float, the effect of the expansion (say) of that air on the occurrence of an increase of temperature will compensate for the alteration in the level of the mercury in the short limb of the syphon resulting from the expansion of the mercury in a syphon barometer having relatively wide upper and lower ends. Mr. Joseph Baxendell informs us that the latest pattern of the new instrument now in use at the Fernley Observatory, Southport, has been rendered practically frictionless, and that the Dines float modifications include a means of overcoming the errors commonly arising from the varying capillary effects occasioned by the reversal of the direction of motion of the mercury in the syphon.

Prof. George A. Gibson, writing in the *Proceedings* of the Edinburgh Mathematical Society, vol. xxii., directs attention to a weak point in the conventional treatment of tangents to circles and curves by the method of limits. In proving the tangent to be perpendicular to the radius, it is shown that when a straight line meets a circle in two points A, B, the line makes equal angles with the radii OA and OB, and since this is the case however near B is to A, it is said, "therefore the same result is true when B coincides with A." But, as Prof. Gibson points out, it would be equally logical to say that if OA is the perpendicular from O on a straight line, E any point on that line, $OE > OA$, however near E may be to A, and "therefore" the same is true when E coincides with A, which is of course absurd. The author remarks, "It is rather disheartening to find the absurdities, so clearly pointed out by Berkeley nearly two hundred years ago, still flourishing and apparently endowed with a new lease of life."

We have received the new volume of Dr. Otto Baschins's "Bibliotheca Geographica," covering the literature of geography to the end of 1900. The new issue does not contain any important new features, but it completes the first decade of a work recognised for its accuracy and exhaustiveness.

The Société d'Encouragement pour l'Industrie nationale has published a valuable paper on the Port of Rosario as a supplement to its May *Bulletin*. The author is M. Georges Hersent, and the paper deals fully with the past, present, and future of the seaport. Useful information about the economic geography of the Argentine generally is also to be found in an introductory chapter.

Among the most important recent additions to the cartography of Canada are a map of south-eastern Alaska and part of British Columbia, showing the award of the Alaska Boundary Tribunal, and a map of the North-West Territories and the province of Manitoba. The former is reduced from the original Canadian Boundary Commission map to a scale of 1 : 960,000, and contours at 1000-feet intervals are retained. The map of Manitoba is on a scale of $12\frac{1}{2}$ miles to an inch.

THE June number of the *National Geographic Magazine* contains a speculative article of considerable interest by Mr. R. A. Harris, in which the author discusses the indications of the existence of land in the vicinity of the North Pole, which are afforded by the known set of the currents in the Arctic Ocean and from observations of the tides. It is argued that a tract of land may exist extending from near the north-west corner of Banks Land, or from Prince Patrick Island, to a point north of New Siberia.

THE first place in the June number of *Petermann's Mitteilungen* is given to a short article on the geography of Tibet by Dr. E. Schlagintweit, accompanying an excellent map of central southern Tibet by Herr C. Schmidt. The map, which is on a scale of 1 : 2,000,000, is compiled from the most recent authoritative data, and the route of the British expedition to Gyangtse is shown. Another valuable paper on Tibet is Herr Richard Tronnier's study of the lives and journeyings of the Jesuit Fathers Johannes Grueber and Albert de Dorville, who crossed Tibet in 1661. This appears in the *Zeitschrift* of the Berlin Gesellschaft für Erdkunde.

DR. W. KOERT, of the Prussian Geological Survey, publishes in the *Naturwissenschaftliche Wochenschrift* for May an illustrated article on his observations of marine deposits and coast-erosion in many portions of the world. Among other interesting results of mineral and organic associations, he notes the formation of structureless calcareous concretions in the modern sand of Dar-es-salam, on the coast of German East Africa. These masses he compares with the "kankar" of Indian geologists.

THE fourth number of the *Boletin del Cuerpo de Ingenieros de Minas del Peru* contains an admirably illustrated account of artesian wells established at Callao. A venture started in 1901 was on the eve of being abandoned, when a copious supply of water was struck at a depth of 46 metres. Other wells have since proved equally successful, and Señor Guillet, the author of this memoir, sounds a note of hope for other areas, when he points out that there were no special geological indications to encourage hydraulic enterprise in the subsoils around Lima.

ACCORDING to the report in a local paper of a meeting recently held at Johannesburg, when Mr. W. L. Sclater, of the Cape Town Museum, occupied the chair, a South African Ornithological Union has been established. The new body has a strong and representative committee, with Mr. Sclater as president, and it is hoped that means will be found for publishing a journal.

WE have received from the United States two pamphlets connected with entomology, the one on some results of the work of the entomological division of the Department of Agriculture (*Bulletin* No. 44), and the other notes by Dr. A. S. Packard on the life-history of the silk-producing moths of the family Saturniidæ, forming No. 22 of vol. xxxix. of the *Proceedings* of the American Academy. Several articles in the former are devoted respectively to aphides affecting grain and grass, and to chestnut and other nut-feeding weevils.

PROF. HUBRECHT, of Utrecht, has favoured us with a copy of an article by himself from the *Jenaischen Zeitschrift* for 1904, dealing with the origin of annelids and chordates, and the systematic position of the ctenophora and platyhelminthes. Numerous debatable points—especially some connected with the "cœlosome"—are discussed in considerable detail, but it must suffice to mention that the author regards ctenophora and platyhelminthes as specialised side-groups, and that in his opinion the fœtal envelopes of mammals are directly derived from invertebrate ancestors, and not from those of birds and reptiles.

IN the *American Naturalist* for April, Dr. Shufeldt compares the various schemes of classification of birds which have been proposed during the last quarter of a century or so, and inquires why these are so different. The answer to the latter question is to be found, he thinks, partly in the homogeneous character of birds in general, and partly in the attempts to classify them in the same manner as other and less homogeneous groups. In this respect all classifications are more or less unsatisfactory, and it is no justification to plead that an "order" of birds has not the same systematic value as a division bearing the same name in mammals. Naturalists must make up their minds what characters are of generic and what of higher value, and then formulate a scheme which can be correlated with the classification of other groups. In another article in the same journal Mr. H. B. Bigelow records the results of certain experiments on goldfish which, in his opinion, prove that these fishes are endowed with the power of hearing.

WE have received Messrs. Merck's annual report on advancements in pharmaceutical chemistry and therapeutics. All the newer preparations and drugs receive notice, and the work contains useful bibliographical and authors' indexes and indications for treatment. No medical man or pharmacist who desires to learn the latest additions to the list of drugs can do without this report.

THE action of snake venom on cold-blooded animals has been tested by Dr. Noguchi in a long series of experiments (Carnegie Institution of Washington, *Publication* No. 12). Three venoms were employed, viz. those of the cobra, water moccasin, and rattlesnake. Snakes and frogs succumb easily to cobra venom, but are relatively insusceptible to the other venoms; turtles are more susceptible to all venoms than the foregoing, and fish are still more so. The grasshopper and some crabs are almost insusceptible, while the lobster is only moderately resistant. Excepting the earthworm, all the worms showed a low degree of susceptibility. The venoms have little effect on the Echinodermata; sea-urchins succumbed, however, but starfish and sea-cucumbers were not perceptibly affected.

"SILAJIT," an ancient Eastern medicine, forms the subject of a paper by Mr. David Hooper (*Journ.* Asiatic Society of Bengal, vol. lxxii., part ii., No. 3, 1903). There seem to be three substances known under this name; one appears as an exudation on the rocks in certain districts of the Himalayas, and consists largely of aluminium sulphate; a second, the black and probably true silajit, is said to form an exudation on rocks in Nepal, and consists mainly of alkalies and alkaline earths in combination with an organic acid related to humic acid; and a third, or white silajit, is apparently of animal origin. The substance is said to be a cure for most disorders. Mr. Hooper desires to direct the attention of other observers to this strange product, as it is possible that it has been met with in other parts of the world.

WE have received the "Year Book" of Livingstone College, of which Dr. Harford is the principal. This useful institution is designed to give to missionaries and others whose life-work may lie in the tropics a training in the elements of medicine, surgery, and hygiene such as may

be useful in districts remote from medical aid. Courses of elementary lectures are also given, both at the college and at the United Service Institution, open to all who may expect to reside or travel in the tropics. The "Year Book" contains details of the college and its curriculum, and useful directions for the preservation of health in the tropics.

In the short notice of Mr. Cecil Hawkins's "Elementary Geometry" in Nature of June 30 (p. 193), reference was made to the absence of numerical answers in the copy supplied. Mr. Hawkins asks us to state that the book is also supplied with answers if desired.

Messrs. T. C. and E. C. Jack, of Edinburgh, have submitted for our inspection four of the plates of a stereoscopic atlas of anatomy, edited by Dr. David Waterston, to be published by them in the autumn. The application of the stereoscopic principle to anatomical illustrations seems, from these examples of it, likely to prove of real assistance to medical and biological students. The plan has already been adopted with success in the teaching of geography and the illustration of books of travel, and there is every likelihood that this further adaptation of the stereoscope to educational work will meet with general approval from lecturers on anatomy. Each stereograph is accompanied by a brief description written by the editor, and the illustration and description are mounted on one card so as to facilitate reference from one to the other. The series will comprise 250 separate stereographs, and these will be contained in cases. The work will be issued at intervals in sections of about fifty stereographs.

OUR ASTRONOMICAL COLUMN.

New Elements and Ephemeris for Comet 1904 *a*.—In No. 55 of the Lick Observatory *Bulletins*, Prof. A. O. Leuschner, of the Berkeley Astronomical Department, gives a set of elements and an ephemeris for comet 1904 *a*, calculated from observations made by Messrs. Aitken, Crawford, and Maddrill on April 17, 22, and 29 respectively.

No. 56 of the same publication contains a second set of elements and an ephemeris calculated by Messrs. Aitken and Maddrill from observations made at Lick on April 17, May 8, and May 24. The following are the elements given:—

$$T = 1904 \text{ March } 6 \cdot 9049 \text{ G.M.T.}$$
$$\left.\begin{aligned}\omega &= 53^\circ\ 27'\ 13''\cdot 8\\ \Omega &= 275^\circ\ 46'\ \ 5''\cdot 5\\ i &= 125^\circ\ \ 7'\ 33''\cdot 1\end{aligned}\right\}\text{Mean equinox of } 1904\cdot 0$$
$$\log q = 0\cdot 432475$$

The ephemeris (for 0h. (G.M.T.) shows that on July 14.5 the comet will occupy the following position in the constellation Canes Ven.:—True $\alpha = 12h.\ 24m.\ 28s.$ True $\delta = +50^\circ\ 37'\ 50''$, and afterwards will travel very slowly in a southerly direction. As the brightness of the comet is now only 0.37 of its original magnitude, only the larger telescopes will be of any use in observing this object.

The Solar Parallax as Determined from the Eros Photographs.—At the meeting of the Royal Astronomical Society on June 10, Mr. Hinks gave an interesting and instructive account of the Cambridge reduction of all the available photographs of Eros obtained during the period November 7–15, 1900. One of the chief features of the paper was a description of the various errors which appeared during the reduction and of the methods employed for their elimination.

The value obtained for the solar parallax in this preliminary result was $8''.7966 \pm 0''.0047$, and this agrees, within the errors of observation, with that previously obtained by Sir David Gill, whilst the probable error is as small as that obtained by him.

Experiments on the Visibility of Fine Lines.—*Bulletin* No. 10 of the Lowell Observatory contains the details and results of a further series of experiments, performed by Messrs. Slipher and Lampland, on the visibility of fine lines at various distances. The experiments were exactly similar to those previously carried out with a fine wire of 0.7 inch diameter, except that a fine blue line 0.7 inch in width, drawn on a white disc 8 feet in diameter, was observed at the same time as the wire. At a distance of 1450 feet, when the angular width of the disc was 19′ and that of the lines was $0''.86$, the wire was certainly seen, but a fictitious line was seen accompanying what was supposed to be the real one.

The general results of the experiments indicated that the wire was more *generally* visible than the line, although at distances less than 400 feet the latter was the more readily seen.

Variability of Minor Planets.—Observations of the magnitudes of the minor planets Iris, Ceres, and Pallas, made by Herr J. Holetschek at Vienna during the years 1899 and 1903, are published in No. 3955 of the *Astronomische Nachrichten*. These show that the magnitude of Iris decreased from 7.4 to 7.6 between November 1 and November 6, 1899. Observing Ceres in April, 1899, it was found that the magnitude on April 9d. 14.5h. was 7.5, on April 13d. 11h. 8.1, and on April 14d. 15h. 6.9.

In the case of Pallas the following magnitudes were observed on the various dates named:—

1903	M.T. (Vienna)	Magnitude
March 23	7 6	8 4
24	7·6	8·7
24	9·8	8·6–8·7
25	7·7	8 4–8·5
26	7·6	8·5

A Variable Star Chart.—In No. 3959 of the *Astronomische Nachrichten*, Prof. Max Wolf publishes 25 charts, each showing the relative position of one of the 25 variables in Aquila mentioned in earlier communications published by him in the same journal. An accompanying table gives the chart number and the number, the position, the variation, and the designation of the comparison star for each variable.

The Leeds Astronomical Society.—No. 11 of the annual *Journal and Transactions* of the Leeds Astronomical Society contains reprints of seven very interesting lectures, on a variety of astronomical subjects, delivered at the society's meetings during last year. A number of letters on current astronomical questions, contributed to various periodicals by the past president, Mr. C. T. Whitmell, are also reproduced. The frontispiece shows a number of photographic reproductions of ancient coins on which were depicted various astronomical symbols, and illustrates a lecture on that subject delivered by Mr. A. Dodgson. The programme of the meetings for 1904 promises some very interesting papers, whilst the report for 1903 shows the society to be in a thriving condition.

"Annuario" of the Rio de Janeiro Observatory (1904).—The twentieth annual publication of the Rio de Janeiro Observatory contains a large amount of useful information on astronomical, meteorological, and general physical matters. The customary calendars and astronomical tables are given in part i. Parts ii., iii., and iv. contain tables of reduction for astronomical and meteorological observations. The usual tables for the conversion of foreign standards are given in part v., whilst the sixth and last section contains many useful records of the local meteorological and magnetic conditions for past years, including the variation of magnetic declination at Rio de Janeiro since 1660.

GEOLOGICAL SURVEYS OF THE UNITED STATES.

Since the appearance of the notice in Nature of December 3, 1903, the following publications of the United States Geological Survey have been received.

1. *Bulletins.*

Of very wide interest is the essay on "The Correlation of Geological Faunas: a Contribution to Devonian Palæontology," by Prof. H. Shaler Williams (*Bulletin* No. 210). The observations are based on a critical examination of the

Devonian rocks of New York, Pennsylvania, and eastern Ohio, as in that region the stratigraphical succession and the continuity of the rocks were sufficiently clear to enable the author and his assistants to work out the relations between the geological formations and the distribution of life. The term fauna is commonly used in palæontology to indicate the list of fossils contained in a single formation, but as the author admits, the limits of formations vary considerably in different localities, and do not coincide with the limits of faunas. He introduces the term *faunule* to distinguish an aggregate of fossils associated either in a single stratum, or in several contiguous strata that may be many feet in thickness—the aggregate being composed of the same set of species. The *fauna*, on the other hand, is defined as an aggregate of local and temporary faunules in which is expressed a common, corporate aggregate of species. The faunule is limited to a single set of conditions. The fauna is to be discriminated by the dominant species, and it preserves its integrity and identity so long in succession, and so far in distribution, as the dominant species retain their ascendancy among their associates. The marine fauna itself is not the universally distributed marine life of a particular epoch, but the fauna of a particular environment of that epoch.

The facts recorded by the author show that migration, not of single species, but of the whole fauna has sometimes taken place. There has been transgression of one fauna over another, thus calling for the assumption that the limits of a formation based upon sudden change in the fossil contents cannot be regarded as synchronous for two parts of even the same province, and, wherever they are thus sudden and sharp, cannot be synchronous with the limits of either the earlier or later fauna in evidence. The detailed study of the migrations and recurrence of species is of the utmost importance, and in this respect alone we have much to learn. The author rightly remarks that for the practical purposes of geological mapping and the descriptions of geological structure the formations are the essential elements, while his statistics demonstrate the intrinsic value of fossils for measuring and indicating geological time. His observations show the necessity for a dual nomenclature—stratigraphical and biological—and they indicate also that "At present we know too little about fossil faunas to be able to predict in what manner their actual time limits will be defined or discriminated, but enough light has already been thrown upon the matter to show that it will be by means of the history which organisms have expressed in their continuous life and evolution that we may expect ultimately to mark off the stages of geological time."

"Notes on the Geology of South-western Idaho and South-eastern Oregon" are contributed by Mr. Israel C. Russell (*Bulletin* No. 217). The notes are the result of a rapid reconnaissance made with the special view of studying the artesian basins; these comprise large tracts of rich agricultural land, throughout which the conditions justify the opinion that flowing water may be obtained. Particular descriptions and illustrations are given of the cinder buttes and craters of the recent, but now extinct, volcanoes. At each of the volcanic centres it seems that the first eruptions were of the explosive type, and that the elevations then produced by the accumulation of projectiles were to a considerable extent buried by the subsequent quiet effusion of vast quantities of liquid lava (basalt).

"Descriptive Geology of Nevada South of the Fortieth Parallel and Adjacent Portions of California," by Mr. J. E. Spurr (*Bulletin* No. 208), contains particulars of a great variety of formations from Archæan to Carboniferous, also of Jura-Trias, Tertiary, and later deposits, as well as of granites, rhyolites, andesites, and other igneous rocks. The work is based on a series of traverses, and is to be regarded as a preliminary survey, as the topographic map is imperfect; but the records of facts observed are full of interest.

"The Geology of Ascutney Mountain, Vermont," is by Mr. R. A. Daly (*Bulletin* No. 209). In this work we have the results of an investigation of the lithology and geology of a plexus of eruptive rocks and of the metamorphic aureole in bordering schistose rocks. The author concludes with hypotheses on the manner of intrusion, on abyssal assimilation, and on the evidences of differentiation of the igneous masses.

"Stratigraphy and Palæontology of the Upper Carboniferous Rocks of the Kansas Section" is the title of a report by Messrs. G. I. Adams, G. H. Girty, and David White (*Bulletin* No. 211). This work summarises the information on the subject, including extensive faunal lists and such data as are available concerning the flora. The plants appear to represent the topmost Carboniferous, if not the so-called permo-Carboniferous, of western Europe.

Economic geology is dealt with in *Bulletins* Nos. 212, 213, 218, 219, 223, and 225. "The Oil Fields of the Texas-Louisiana Gulf Coastal Plain" are fully described by Messrs. C. W. Hayes and W. Kennedy; "The Coal Resources of the Yukon, Alaska," are discussed by Mr. A. J. Collier, who considers that with proper development there will probably be sufficient coal to supply local demands for some time to come; "The Ore Deposits of Tonopah, Nevada," are reported on briefly by Mr. J. E. Spurr, who points out that the most important mineral veins occur in the early Tertiary andesites, and that the values in the ores are entirely gold and silver; "Gypsum Deposits in the United States," by G. I. Adams and others, are treated with especial reference to economic conditions; and "Contributions to Economic Geology," 1902 and 1903, have been prepared by a number of authors under the direction of Messrs. S. F. Emmons and C. W. Hayes; these contributions relate to metalliferous deposits, coal, oil, gas, stone, cements, clays, fuller's earth, gypsum, phosphates, mineral paints, &c.

In *Bulletin* No. 220, Mr. F. W. Clarke has tabulated the "Mineral Analyses from the Laboratories of the U.S. Geological Survey, 1880 to 1903."

In *Bulletins* Nos. 214, 215, 216, 221, 222, 224, and 227, we have a catalogue and index of the publications of the United States Geological Survey, 1901 to 1903; bibliography and index of North American geology for 1902; catalogue and index of the publications of the Hayden, King, Powell, and Wheeler surveys; results of primary triangulation; geographic tables and formulas; gazetteer of Texas, edit. 2; and "The United States Geological Survey, its Origin, Development, Organisation, and Operations."

II. *Monographs.*

Monograph No. 44 contains the last work of Prof. Alpheus Hyatt, the "Pseudoceratites of the Cretaceous"; this was almost ready for the printer at the time of his death in January, 1902, and it has been edited by Mr. T. W. Stanton. It is illustrated by 47 plates, and these, together with the descriptions of species and the reference of these and other species to new genera of Ammonoidea, were arranged or selected by the author. As the editor remarks, "The multiplication of families, genera, and species will be understood by all who are acquainted with Professor Hyatt's habit of attempting to express in the terminology every important fact observed in the course of his investigations." In some cases the classification of the forms is incomplete, as the author's opinions on certain questions had evidently become much modified since his previous publications. The Pseudoceratites he speaks of as "an artificial group, including for convenience of treatment all the retrogressive genera of the Cretacic that have sutures with simple outlines resembling those of Triassic cephalopods, formerly included under the name Ceratites." Among the British forms referred to is *Ammonites* (*Mantelliceras*) *Mantelli*, of Sowerby.

Monograph No. 45 is on "The Vermilion Iron-bearing District of Minnesota," by Mr. J. Morgan Clements, and it is accompanied by a folio atlas of geological, mining, and topographic maps. This great iron-bearing district has an area of, approximately, 1000 square miles in north-eastern Minnesota, and it resembles the other iron-bearing districts of the Lake Superior region in that the rocks are of great geological antiquity. Iron ore was first noticed in the district in 1850, but its economic importance was not realised until long subsequently. The ores occur in four areas, one of which includes the Giant's Range, which attains a height of 2120 feet above sea-level. The rocks comprise Archæan, divided in ascending order into the Ely greenstone, the iron-bearing Soudan formation, and various granites. The greenstones, though highly altered, are largely of volcanic character, but with them are associated

some intrusive rocks which present in many cases a schistose character. The Soudan formation, the oldest sedimentary group in the district, is bent into prominent anticlines, but is otherwise intricately contorted and infolded with the greenstones; it comprises conglomerates with fragments of the older greenstones, and an outlying group of siliceous rocks, largely white cherts, with red jasper and carbonate-bearing chert, grünerite-magnetite-schist, blue hematite, magnetite, and small quantities of pyrite. The cherty rocks are banded, and the hematite occurs in certain places in masses of variable size, which constitute the ore deposits. These iron-bearing rocks are considered to be of sedimentary origin. The source of the iron was, in the first instance, the Ely greenstone. From this it was removed through the action of water and collected to form part of the sedimentary marine deposits of the Soudan formation. After the folding of the rocks this disseminated iron was carried by downward-percolating waters into places favourable for its accumulation. The methods of mining are described. There are descriptions also of the later intrusive rocks, of the Huronian and Keweenawan series, of the drifts, the Glacial lakes, and other topographic features.

Monograph No. 46, on "The Menominee Iron-bearing District of Michigan," by Mr. W. S. Bayley, is the sixth and last of a series of reports on the iron-bearing districts of the Lake Superior region. The area now described is a very important one, as it has yielded since 1877 nearly thirty millions of tons of iron-ore of Bessemer grade. The rocks comprise Archæan schists and granites, which appear on the borders of the district; in the central portions the iron-bearing Algonkian rocks, with basal conglomerate, occupy a trough of highly folded rocks, distinguished as the Lower and Upper Menominee series, there being a marked unconformity between them. These divisions correspond to the Lower and Upper Marquette series, and to the Lower and Upper Huronian of other areas. Above these folded rocks lie horizontal Palæozoic beds, comprising the Lake Superior sandstone and an Ordovician limestone. The Lower Menominee series comprises quartzite and dolomite, the latter affording a key to the folding. The gap between Lower and Upper Menominee series is marked by conglomerate at the base of the Upper series, which contains pebbles of jaspilite (iron-bearing), and these are taken to represent the Negaunee formation. The Upper Menominee series comprises also slates, quartzites, and jaspilites, these last-named being banded rocks composed of alternating layers of red jasper and ore-deposits. It is noted that the larger ore-deposits all rest upon relatively impervious foundations, which are in such positions as to constitute pitching troughs. The processes of concentration were the same as those worked out in other districts by Van Hise, being due to descending waters flowing in definite channels. The concentration was commenced after the folding of the rocks, and completed before the beginning of the Upper Cambrian. The subject is treated very fully from all points of view, structural and physiographic as well as economic, and it is profusely illustrated with maps, sections of the strata, microscopic sections of rocks, and pictorial views. There are also two plates of possible organic markings from the iron-bearing rocks of Chapin Mine; these were thought by Mr. W. S. Gresley to represent impressions of plants, track-marks, &c.

III. *Professional Papers.*

The United States Geological Survey has issued a series of "Professional Papers," of which we have received several examples. No. 11 is on "The Clays of the United States East of the Mississippi River," by Mr. Heinrich Ries. It is interesting to note that while kaolins occur in several States, the local output at present is insufficient to meet the demand. No. 12, by Mr. F. L. Ransome, deals with the "Geology of the Globe Copper District, Arizona." No. 13 is on "Drainage Modifications in South-eastern Ohio and Adjacent Parts of West Virginia and Kentucky," by Mr. W. G. Tight. The subject is one which attracts a considerable amount of interest, so far as it illustrates the history of rivers and the relation of the old to the present river systems. The author concludes that the high-level valleys of the region represent a connected system of an old drainage cycle which antedates the first advance of the ice of the Glacial period; that the deposition of the silts on the old valley floors and the deflection of the streams producing the present drainage system were due to the action of the advancing ice-sheet of the first Glacial epoch; that the extensive erosion of the present river valleys to depths below the present drainage lines was accomplished during an inter-Glacial interval of great duration; and that these inter-Glacial valleys were partially filled with débris by the flood waters of the last Glacial epoch, the post-Glacial erosion being represented by the channels cut in the floor of these deposits since the rivers have acquired their present volume. Paper No. 14, by Mr. Henry S. Washington, comprises a laborious but most useful work, entitled "Chemical Analyses of Igneous Rocks Published from 1884 to 1900, with a Critical Discussion of the Character and Use of Analyses." The analyses follow on from the last date of publication of Roth's "Tabellen," and include a few analyses of 1883 omitted from that work. The author insists on the importance of careful and precise work, lamenting that rock analyses are too often entrusted to inexperienced students. The work will be of the greatest value to petrologists. Paper No. 15 is on "The Mineral Resources of the Mount Wrangell District, Alaska," by Messrs. W. C. Mendenhall and F. R. Shrader. It deals with the occurrence of ores of copper, gold, silver, platinum, tin, mercury, osmiridium and iron, and also with a few indications of coal or lignite.

No. 16 is on "The Carboniferous Formations and Faunas of Colorado," by Mr. G. H. Girty. This work is based on the extensive collections of fossils of the Geological Survey and the National Museum, and its purpose is to ascertain, by means of the invertebrata, their grouping into local and formational faunas. It brings out the close relation which existed in Carboniferous time between the Colorado seas and those of the Mississippi valley. The Leadville, Millsap, and Ouray limestones which form the base of the Carboniferous, and which include a part of the Mississippian fauna, include also in their lower portion a distinctive Upper Devonian fauna. The Lower Carboniferous was followed by an epoch of elevation and erosion, and none but the early portion of the Mississipian time is represented in the Colorado sediments. This lower group comprises (1) the Weber formation, of dark carbonaceous shales and thin limestones, with fossils of Coal-measure type, and (2) the Maroon formation, a great series of conglomeratic beds and grits, surmounted by red sandstones. The same difficulties that have been met with in Britain are encountered in Colorado, and the author discusses at some length the question whether certain red beds are Carboniferous, Permian, or Triassic. The Wyoming "Red Beds series" appears to succeed the Maroon formation in places without a break, but the author regards it as really Triassic. The numerous descriptions of fossils are accompanied by ten plates.

No. 17, by Mr. N. H. Darton, is a "Preliminary Report on the Geology and Water Resources of Nebraska West of the 103rd Meridian." The geology and topographic features are described, and some remarkable monuments of erosion known as the Chimney rock, the Smokestack rock, and the Twin-sisters are represented on photographic plates. There is also a figure of the Titanotherium, which is found in the basal portion of the Tertiary strata.

In No. 18, Mr. J. P. Iddings contributes an essay on "Chemical Composition of Igneous Rocks Expressed by Means of Diagrams with Reference to Rock Classification on a Quantitative Chemico-mineralogical Basis." In introducing this work Mr. Whitman Cross remarks, "As a successful attempt at the elucidation of a complex problem the paper is of importance to all students of igneous rocks."

In No. 19, "Contributions to the Geology of Washington," by Mr. G. O. Smith and Mr. Bailey Willis, the authors deal chiefly with the origin of the physical features. No. 20, "A Reconnaissance in Northern Alaska," by Mr. F. C. Shrader, with notes by Mr. W. J. Peters, contains much interesting information about tracts hitherto unexplored. Among the rocks described are Silurian, Devonian, Carboniferous (?), Jura-Cretaceous, Cretaceous, and Tertiary, as well as Drift deposits. The mineral resources, climate, population, and other subjects are dealt with.

IV. *Reports.*

Part i. of the twenty-fourth annual report for 1902–3 contains an account of the progress of the Survey by Mr. C. D. Walcott, director, who refers to the increase of work, and to the establishment of a separate hydrographic department under the charge of Mr. F. H. Newell. An obituary memoir, accompanied by a portrait, is given of Major J. W. Powell.

The detailed report on the "Mineral Resources of the United States," for 1902, by Mr. David T. Day, shows a continuation of the remarkable activity in the mineral industries, the total value exceeding one thousand million dollars—iron and coal being the most important products. There was a notable increase in the production of uranium and vanadium minerals, and these were nearly all shipped abroad in the crude state as mined. The production of bauxite was largely increased, while that of monazite, obtained chiefly from North Carolina and partly from South Carolina, showed a slight increase over the previous year. The production of crude petroleum and of natural gas also showed increase.

V. *Local Surveys.*

The Wisconsin Geological and Natural History Survey has sent copies of *Bulletins* Nos. 11 and 12. The former is a "Preliminary Report on the Soils and Agricultural Conditions of the North-central Portion of the State," by Dr. S. Weidman. It is illustrated by a soil map, on the scale of an inch to three miles, and this gives the general character of the soil over different "soil formations" or subsoils—in reality various alluvial and drift deposits. No. 12 is by Mr. C. D. Marsh on "The Plankton of Lake Winnebago and Green Lake," lakes of different types, one shallow, the other deep. As bearing on the question of fish-production, it is noted that Entomostraca, which furnish the basis of food for fishes, are more numerous in the deep than in the shallow lake.

We have received also vol. xiii. of the *Memoirs* of the Iowa Geological Survey, being the annual report for 1902 with accompanying papers. The papers comprise descriptions (seven in number) of various counties, by the State Geologist, Mr. Samuel Calvin, and his assistants. There is also a discussion of the requisite qualities of lithographic limestone, with a report on tests of the lithographic stone of Mitchell County, Iowa, by Mr. A. B. Hoen. The report is accompanied by a colour-printed plate drawn on the local stone and illustrating the quarry from which it was obtained. The sample, submitted for trial, was not wholly satisfactory, inasmuch as it was noticed in trueing the stone for printing that the surface-plane intercepted planes of bedding at small angle, but there is reason to hope that, as the stone is worked, larger and more perfect slabs may be obtained. H. B. W.

DISINFECTING STATIONS.

An interesting article upon disinfecting stations, written by Prof. Henry R. Kenwood and Mr. P. J. Wilkinson, appears in the most recent issue of the *Journal* of the Sanitary Institute (vol. xxv., part i., April; London: Offices of the Sanitary Institute, Parkes' Museum, Margaret Street, W.).

It is now well recognised that the disinfection of textile articles can be effected by the use of steam more quickly, more certainly, and with less damage to the article disinfected than by the use of any other agent; and a steam disinfecting station is now considered an essential provision by sanitary authorities. As the steam penetrates into the interstices of the colder articles it undergoes condensation, and imparts its latent heat instantaneously to the colder objects in contact with it. Steam thus condensed into water occupies only a very small fraction (about 1/1600) of its former volume, and to fill the partial vacuum thus formed more steam presses forward, in its turn becoming condensed and yielding up its latent heat, and so on until the whole mass has been penetrated.

Saturated steam may be used as current steam at about atmospheric pressure; but there is an advantage, in point of time, in the employment of steam disinfecting apparatus in which saturated steam is used under pressure, and higher temperatures are thereby obtained, when very highly resistant organisms have to be destroyed.

The time required for disinfection by steam obviously depends upon the resistance of the organism to be destroyed, the bulk of the infected articles, and the pressure of the steam employed. The best researches indicate a pressure of 10 lb. (and therefore a temperature of 115° C.) for twenty minutes as trustworthy in general practice.

The steam may be generated in a special boiler, from whence it is conducted to the disinfecting chamber, and such a boiler is sometimes made to supply steam for laundry purposes; or the lower part of a jacketed oven may be filled with water, and by firing directly under the machine the steam may be raised in the jacket of the disinfector itself. This arrangement favours compactness and economy, but a separate boiler is more accessible for cleansing and repairs.

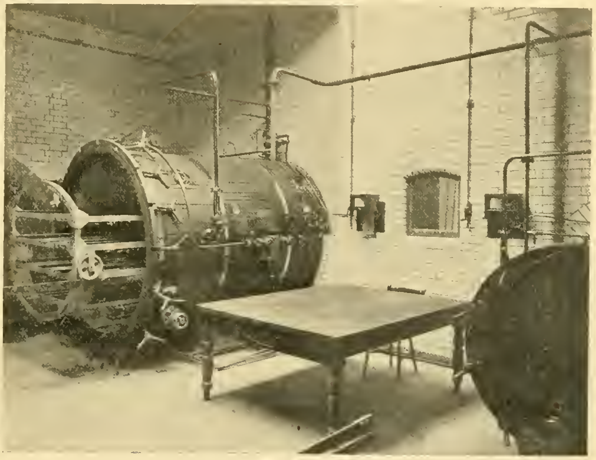

FIG. 1.—Interior of non-infected Chamber at the Fulham Disinfecting Station.

The various stoves now employed for disinfecting by steam may be classified as follows:—

(1) Stoves in which steam without pressure is employed. These are, of course, the simplest and cheapest.

(2) Those in which steam at low pressure (2, 3 or 5 lb. per sq. in.) is used. Although the temperature of 110° C. which can be reached by some of these stoves is generally sufficient, a higher temperature can never be employed in them. These stoves, though cheaper, meet with less general acceptance in this country than

(3) Those in which steam at high pressure (10 lb. and over) can be employed.

A temperature of 115° C. to 120° C. can be obtained in these stoves, and an exposure of articles for about twenty minutes will suffice for disinfection.

A disinfection station should comprise:—

(1) Two rooms completely separated from each other by

a wall, into which the oven is built, so that it communicates with both rooms. In one chamber the infected articles are placed in the oven, and when disinfection is complete the articles are taken out in the other chamber.

(2) An incinerator or destructor for the combustion of useless infected articles.

(3) Separate sheds for (*a*) vans employed to bring infected articles, and (*b*) vans employed to return disinfected articles.

(4) A laundry and bath-room.

The article describes the forms of stoves mostly used in this country at the present day, the planning and construction of the disinfecting station, the staff, the disinfection of articles (leather goods, furs, feathers and books) which are injured by steam, the destruction of useless articles in a destructor furnace; and much useful information as to cost is also given.

The article is well illustrated. The illustration here reproduced shows the non-infected chamber; the door of one of the ovens is open, and the wheeled carriage running on internal rails is seen with the racks on which the clothing and bedding are placed. The observation window in the partition wall is permanently closed.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

The physiological laboratory of the University of London will remain open for post-graduate research students during the vacation months August and September. Foreign graduates who may be desirous of working in the laboratory should previously communicate with the director or with the academic registrar of the university.

A course in practical and clinical bacteriology will be held at King's College, University of London, from Wednesday, August 3, to Saturday, August 13. The course will consist of lectures, demonstrations, and practical work; in the latter, the members of the class will make for themselves permanent preparations of the chief pathogenic micro-organisms, and will carry out the principal manipulations employed in bacteriological investigations. Names should be sent in as soon as possible to the secretary or to Prof. Hewlett.

We directed attention a short time ago (June 9, p. 138) to the new illustrated quarterly review *Buddhism*; in the third number is an interesting article on education in Burma, in which it is stated that the vernacular lay schools introduced by the British Government are by no means an unqualified success, since they have been organised without due regard for native conditions. "What object," says the anonymous writer, "has education to a jungle Burman except to form his character? And can Burmese character be moulded by studying the history or geography of Europe or standard readers garbled under European supervision? A Burman should be taught Burman ethics, morals and usage. The disobedience to the authority of parents, which is so alarming a feature in the present state of things, requires to be specially dealt with. The evil goes beyond mere disobedience and truancy—cases where boys rob their parents or wantonly commit other breaches of the law are increasing." Evidently Burma also is suffering from that peculiar British attitude of mind that seeks to constrain all peoples to conform to the ideals and methods of the Britons themselves.

SOCIETIES AND ACADEMIES.

London.

Royal Society, June 9.—"On the Action of the Venom of *Bungarus coeruleus* (the Common Krait)." By Major R. H. **Elliot,** I.M.S., W. C. **Sillar,** M.B., B.Sc., and George S. **Carmichael,** M.B., Ch.B.

Experiments were performed by the authors in the pharmacological laboratory of the University of Edinburgh with the following results:—

(1) The minimum-lethal dose of the dried venom was determined for frogs and small mammals, rats and rabbits. It was found that the M.L.D. for the frog was about 0·0005 of a gram per kilo., for the rat 0·001 gram per kilo., and for the rabbit the remarkably low dose of 0·00008 gram per kilo.

(2) It was found that Calmette's anti-venomous serum in quantities sufficient to protect rats against ten minimum lethal doses of cobra venom, in the same quantities was quite powerless to protect these animals from similar doses of krait venom.

(3) The condition of various nerve terminals was studied, both in animals that die after poisoning by krait venom and in nerve muscle preparations from the frog, and it was found that the integrity of these nerve ends was invariably involved at a comparatively early stage in the poison.

(4) The blood was carefully examined, and no evidence of antemortem clotting or intravascular hæmolysis was discovered.

(5) The action of krait venom was examined when its solution was perfused through the isolated vessels and heart, respectively, of the frog. It was found that this venom, while resembling in action that of cobra venom, differs greatly in the degree of constriction of vessels and enhancement of ventricular contraction produced. Cobra venom exercises an action in these directions many times greater than that of krait venom. Cardio-plethysmographic tracings are shown.

(6) Studying the manner in which the vital functions of mammals (rabbits, cats, and dogs) are influenced when exposed to the action of this venom, the authors show by means of kymographic and plethysmographic tracings that the vaso-motor centre is strongly affected, a suspension of the activity of this centre, as shown by the great splanchnic dilatation, rapidly ensuing after its transient stimulation. There are also indications of a feeble cardio-inhibitory action. The experiments and illustrative tracings likewise show that death is brought about by destroying the activity of the respiratory centre.

(7) From these results the conclusion may be arrived at that while the symptoms produced by krait poisoning are similar to those of cobra poisoning, they differ so much in relative degree as to render it doubtful if they can properly be spoken of as identical.

"Contributions to the Study of the Action of Sea-snake Venoms. Part i." By Sir Thomas R. **Fraser,** M.D., F.R.S., and Major R. H. **Elliot,** I.M.S.

The venoms used in the research were those of *Enhydrina Valakadien* and *Enhydris Curtus*.

The minimum-lethal doses of *Enhydrina Valakadien* venom were found to be:—for rats = 0·00009 gram per kilo. of body weight, for rabbits = 0·00006 gram per kilo. of body weight, for cats = 0·0002 gram per kilo. of body weight.

The minuteness of these doses indicates that sea-snake venom is the most lethal of all substances the lethal power of which has been determined.

Symptoms of Sea-snake Poisoning in Animals.—In the main these symptoms resemble those of cobraism, but the dyspnœa is more urgent.

Summary of Results.

(1) Enhydrina venom has no direct action on the walls of the arterioles, or at least has no action in any strength of solution which could be present in the blood of a human victim of sea-snake bite.

(2) Enhydrina venom acts directly on the isolated frog ventricle, producing a tonic and stimulating effect, but this action is produced only by very strong solutions (1 : 5000). The heart-beat is quickened, and the result is therefore similar to that produced by very weak solutions of cobra venom (1 : 1,000,000 or weaker).

(3) By experimenting with the mammalian heart exposed *in situ*, the authors have shown that Enhydrina venom has no direct action on the vagal cardio-inhibitory centre. This affords a striking contrast to the condition observed in cobra poisoning. In the latter case, the powerful tonic and stimulant action of the venom on the heart-muscle (or more probably on its nerve-ends) is masked by equally powerful and direct stimulation of the cardio-inhibitory centre. In Enhydrina poisoning, on the other hand, the complete absence of cardio-inhibition leaves the feeble tonic action on the heart free to manifest itself, as appears to be displayed in several of the tracings. The authors cannot

otherwise explain the increase in rate of the heart-beats which they not infrequently met with in their experiments.

(4) Enhydrina venom has apparently no direct action on the vaso-motor centre.

(5) The blood-pressure curve in Enhydrina poisoning is a remarkably steady one, provided that moderate doses of venom are given and that care is taken to avoid the injection of large volumes of fluid into the blood vessels. This is due to the fact that the blood pressure is exposed neither to the influence of the rival forces which act on the heart so strongly in cobraism, nor to the direct vaso-motor changes which characterise the action of certain other venoms.

(6) The respiratory mechanism is that which is chiefly affected by Enhydrina venom. If large lethal doses are employed respiration falls rapidly, and a considerable rise of blood pressure, asphyxial in origin, may precede death. The heart-beat then quickly slows, and blood pressure falls with corresponding rapidity.

Obviously, these are simply the phenomena of rapid asphyxiation. If, however, smaller lethal doses of venom are employed, no marked rise in blood pressure occurs. The ordinary level is maintained until near the occurrence of death; the beat then slows, and the blood pressure falls. Here we have an expression of gradual cardiac failure, brought about by slowly progressive asphyxiation. The absence in slow Enhydrina poisoning of the large asphyxial rises of pressure which are so characteristic of the final stages of cobra poisoning is readily explained by the fact that Enhydrina venom has no direct constrictive action on the walls of the arterioles, such as cobra venom possesses.

(7) As to the part of the respiratory mechanism that is affected by sea-snake venom, the rapidity with which respiration is affected, both when venom is injected into a vein and also when it is applied directly to the medulla oblongata, leaves no room to doubt that the respiratory centre is directly acted on by the venom. On the other hand, some degree of motor nerve-end paresis is constantly present in animals dying from the effects of subcutaneous injections of this venom. The fact is emphasised that, in experiments carried out by dropping venom on the exposed medulla oblongata, animals were not killed through the respiratory centre with their motor nerve-ends still undamaged. In this respect, Enhydrina venom differs in its action from cobra venom. It would therefore appear that, in poisoning with Enhydrina venom, motor nerve-end paresis plays a much greater part than it does in cobraism. It is not difficult to suppose that a blunting of the motor nerve-end mechanism, even though far from absolute, may seriously add to the embarrassment of a centre which has already been directly and gravely enfeebled.

"On the Structure and Affinities of Palæodiscus and Agelacrinus." By W. K. **Spencer,** B.A., F.G.S. Communicated by Prof. W. J. Sollas, F.R.S.

The method employed was that devised by Prof. Sollas (*Phil. Trans.*, B, vol. cxcvi.). This method introduces a new field of research to palæontologists, for an accurate model of the internal parts of fossils may be made by the investigator. Specimens of the above genera were ground by a special machine at uniform distances of 1/40th mm., and each successive surface photographed. From tracings of the photographs obtained wax models were built.

Palæodiscus and Agelacrinus were chosen for investigation because many observers have claimed them as possessing primitive and ancestral characters.

Palæodiscus is one of the oldest echinoids known, occuring in the Lower Ludlow beds of Leintwardine. It is shown to possess features which are only found in embryonic echinoids of the present day.

No interambulacral plates are present in the peristomial region. The interambulacrum possesses only a single initial plate proximally to the mouth. The vast majority of the plates of the interambulacrum are rhomboidal. The outer surfaces of the pyramids are concave. Other Palæozoic echinoderms may possess these characters, as shown by Jackson, but no other echinoid possesses so many undoubtedly primitive characters. This makes the important discovery of Prof. Sollas (confirmed by the author), that there are two series of plates in the ambulacrum, much easier to understand. The outer series was compared to the true echinoid ambulacrals, the inner series to the asteroid ambulacrals. Palæodiscus would then be placed at the base of the echinoid stem, and would enable us to derive the echinoids from asteroid ancestors. The asteroid series of plates of Palæodiscus is represented in other echinoids by the auricles which were shown by Lovén to have an independent origin and growth. It is noteworthy that this comparison was instituted by Johannes Müller so long ago as 1853.

Agelacrinus is a member of the recently revived group of the Edrioasteroidea. This group has been claimed as ancestral to free moving echinoderms by Neumayer, Haeckel, and Bather. The genus Edrioaster, on which most of the previous investigations have been conducted, lends support to this suggestion, for it possesses a double series of flooring plates to the ambulacral groove between which are pores. It was therefore suggested that since the Edrioasteroidea alone amongst Pelmatozoa possessed pores through which the eleutherozoan ampullæ could be protruded, they were the pelmatozoic ancestors of the free moving echinoderms.

Agelacrinus is shown, however, to possess single flooring plates, and no pores are present either through or between these plates. The pores of Edrioaster, therefore, are not so characteristic or important a feature of the Edrioasteroidea as the above authors would claim.

In conclusion, it is pointed out that the Asteroidea are the most primitive Eleutherozoa, and their structure is much too simple to be derived directly from any known pelmatozoan.

June 16.—"On the Relation between the Spectra of Sunspots and Stars." By Sir Norman **Lockyer,** K.C.B., F.R.S.

In a previous paper on the chemical classification of the stars the author suggested the probability that, as the result of further work, the "genera" then proposed might have to be split up into "species." During more recent researches the temperature classification was tested by comparing the relative intensities of the red and ultra-violet ends of the spectra of stars, situated on various horizons of the temperature curve, including Capella and Arcturus, which, according to the original general classification, belong to the same type, viz. "Arcturian." It was found that the spectrum of Capella extended on an average about 70 tenth-metres further into the ultra-violet than that of Arcturus, whilst the red portion of the spectrum is certainly stronger in the latter. That is to say, *the general temperature of Arcturus is probably appreciably lower than that of Capella.*

The next step was to see if chemical change accompanied this reduction of temperature, and if so, whether the change was in any way related to the change from the photosphere to the sun-spot spectrum. In comparing, for this purpose, the spectra taken with the 6-inch Henry prismatic camera, it was noticed that certain lines were relatively intensified in passing from the spectrum of Capella to that of Arcturus.

Similar comparisons of the Fraunhoferic spectrum with the spectra of Capella and Arcturus respectively were next made. This work led to the following conclusions:—(1) That the line absorptions of Capella and the sun are practically identical; (2) that although, speaking generally, the same lines occur in the spectra of the sun and Arcturus, yet in the latter many lines are relatively more intense than in the former. Moreover, in the great majority of such cases *the lines so intensified are probably due to vanadium and titanium.*

Now an analysis of the widened lines observed in sunspots since the year 1894 has shown that the *elements chiefly affected are also vanadium and titanium.*

Thus it will be seen that whilst the temperature classification certainly places Arcturus on a lower temperature level than Capella, and, therefore, the sun, the evidence obtained from a study of the line absorptions of Arcturus and of sun-spots indicates very clearly that the temperature of the Arcturian absorbing atmosphere is about the same as that of the sun-spot nuclei during the above-mentioned period. This conclusion justifies the ideas formulated by De la Rue, Stewart, and Lœwy that the spots are produced by the downrush of cooler material.

Reference is also made to Prof. Hale's suggestion that because the lines which are widened in sun-spots appear as

strong dark lines in Piscian stars, the effect may be produced because sun-spots are more numerous in such stars. From the evidence adduced above it seems a far more probable explanation to suppose that these lines are intensified in sun-spots, and strengthened in those stars which have been placed on lower temperature levels than the sun, because the general temperature conditions are similar. That is to say, the fall of temperature experienced by the metallic vapours in passing from the photosphere to the spot nucleus is of the same order as that to which an absorbing atmosphere is subjected in passing from the temperature conditions of Capella or the sun to those of Arcturus or the lower temperature stars.

"An Experiment Illustrating Harmonic Undertones." By H. **Knapman.** Communicated by Dr. G. J. Burch, F.R.S.

If a vibrating tuning-fork is pressed against a light object such as a piece of paper or a stretched string, this object may follow the vibrations of the fork, contact being continuous. This use of a tuning-fork is mentioned in Lord Rayleigh's "Theory of Sound," § 133. In the present experiment a lightly poised piece of paper is touched by the fork; with small pressure contact may be broken during part of each vibration, and the paper gives a note resembling that of a bowed violin-string, in which harmonic overtones are strong. With still less pressure, contact may be made only at every other vibration of the fork, when the paper gives a note an octave below that of the fork. Similarly, contact at every third vibration of the fork gives the twelfth below, and so on. We thus have the series of harmonic undertones, and with a c'' fork ten or more may be made easily audible.

An optical method of examining the vibrations is also described. A large tuning-fork was made to touch a small card, the edge of which was observed with a lens against a dark background, and appeared to be drawn out into a continuously shaded band, in which stationary positions were visible. The characteristics of various states of vibration were readily perceived.

Geological Society, June 22.—Dr. J. E. Marr, F.R.S., president, in the chair.—The igneous rocks of Pontesford Hill (Shropshire): Prof. W. S. **Boulton.** The hill is a "plagioclinal ridge," bounded on all sides by faults; it is made up entirely of igneous rocks. There are two distinct groups of igneous rocks: a bedded group, consisting of rhyolites and acid tuffs, with andesites and andesitic tuffs, and an intrusive group of olivine-dolerites. The northern end of the hill consists of rhyolite. The andesitic group is made up of felsitic-looking tuffs, passing up into andesitic tuffs, hälleflintas, and lavas. The intrusive rocks are basic and often amygdaloidal; they compare in composition with such olivine-dolerites as those of Rowley, the Clee Hills, and Little Wenlock.—The Tertiary fossils of Somaliland, as represented in the British Museum (Natural History): R. B. **Newton.** The new material described is that in the Donaldson-Smith collection, and one presented by Major R. G. Edwards Leckie. The large Lucinidæ and specimens of Campanile (previously considered as Nerinæa) are typical of Eocene rocks generally, and they agree with the Foraminifera in the Somaliland Limestones in supporting the reference of these rocks to this period. Two limestones seem to be represented in the collections, and appear to be capable of correlation with those of the south-eastern corner of Arabia, as well as with those of Sind and Cutch. Six new species are described and named, and sixteen species or varieties described.—The Caernarvon earthquake of June 19, 1903, and its accessory shocks: Dr. C. **Davison.** This earthquake was the strongest disturbance indigenous to the county for more than five centuries. Its disturbed area contained about 25,000 square miles. The centre of the innermost isoseismal (intensity 7) was situated beneath the sea, about 4 miles west of Pen-y-groes, and the longer axis of the isoseismal ran from N. 40° E. to S. 40° W. It is concluded that the earthquake was caused by a slip of about 16 miles in length along a fault running in the above direction, hading north-westward, and passing either through Clynnog or a mile or two either to the north-west or south-east.

Challenger Society, June 29.—Sir John Murray in the chair.—The **Chairman** exhibited the skeleton of a problematical organism, possibly allied to Heliopora, from the sea bottom off Cuba, and read a letter on its structure from the late Prof. Alleyne Nicholson.—Mr. E. W. L. **Holt** exhibited some new and rare Crustacea from the Atlantic. Mr. Holt also read a paper on the Schizopoda of the North Atlantic and its eastern slope, from the collections by Mr. George Murray in the *Oceana*, by Dr. G. H. Fowler in H.M.S. *Research* in the Færöe Channel and the Bay of Biscay, and by himself in the *Helga* off west Ireland. These collections included a number of interesting novelties, notably among those forms which appeared to live actually on the bottom in deep water, and were caught by a tow-net attached to the trawl-rope.—Mr. Stanley **Gardiner** opened a discussion on the distribution of marine larvæ, in which, mainly from his own observations, he dealt with their length of life in reference to their populating banks and shores in the Indo-Pacific and Atlantic Oceans. He concluded that the larvæ of Crustacea and Echinoderms other than Crinoids may be expected to reach almost any bank, but that results in geographical distribution may be expected from Cœlenterata and Turbellaria, and to some degree also from Chætopoda, Gephyrea, and Mollusca.

Edinburgh.

Royal Society, June 6.—The Hon. Lord M'Laren in the chair.—An obituary notice of Dr. Charles Gatty, prepared by Prof. W. C. M'Intosh, was read.—Dr. E. G. **Coker,** McGill University, Montreal, communicated a paper on the measurement of stress by thermal methods. The paper was experimental, investigating on the one hand the effect of tension upon the coefficient of thermal expansion, and on the other the change of temperature accompanying the application of various kinds of stress. The changes of temperature were measured thermoelectrically, corrections being applied for the loss of heat by conduction, radiation, &c., as the stress was being applied. A number of results were established, the most interesting being, perhaps, the fact that the rate of heat production during the development of the strain continues constant even after the limit of elasticity has been exceeded. As regards the effect of stress on the coefficient of expansion, it was found that there was no appreciable change.—A paper was read on the spectrum of Nova Persei and the structure of the bands, as photographed at Glasgow, by Prof. **Becker.** In the earlier photographs before August, 1901, the spectrum suggested a number of bright bands fading towards the ends and overlapping one another. In the later photographs the bands become detached and suggest a line spectrum in which the lines have broadened into bands. The broadening was found to be proportional to the wave-length, and independent of the nature of the element. The sequence of alternate maxima and minima which characterised the bands, and the distances separating these, were found to be also proportional to the wave-length. This is in accordance with Doppler's principle if we assume the effects to be due to motion in the line of sight. An important part of the paper was devoted to a mathematical demonstration of the correctness of the assumption that the resultant intensity at any point of the plate where several bands are superposed is the sum of the intensities which the radiations would singly produce. The general conclusion was that the spectrum was due to hydrogen and helium.—In a note on astronomical seeing, Dr. **Halm** directed attention to Langley's ingenious method for improving definition in a telescope by agitating the air in the tube. This result, at first sight so contradictory to all preconceived ideas, suggests consideration as to the condition of the atmosphere as a whole when the best definition is obtained. The cause of the blurring is no doubt due to the changes of refraction which accompany the movements of the air. If every portion of the moving air came to its new position with exactly the temperature and density which belong to the new position, there would be no change of refraction and consequently no blurring. Now this state is realised when the air is in a condition of convective or adiabatic equilibrium, and hence definition will be clearer the more

nearly the atmosphere approximates to this condition. Definition is often very good when gales are blowing, and there is no doubt as to the better definition in summer than in winter. These and other cases seem capable of explanation along the lines indicated.

June 20.—The Hon. Lord M'Laren in the chair.—A paper was communicated by Lord **Kelvin** on the front and rear of a free procession of waves in deep water. A solution of the differential equations was obtained which represented a set of standing waves on an infinite sheet of water. At time zero this set of standing waves was conceived as taking place over one-half, to the left (say) of a line drawn parallel to the ridges, while the rest of the surface to the right was initially at rest. The standing waves were then decomposed into two equal processions moving respectively to the right and to the left. At any finite time after there would be a point to the right up to which the motion would be sinusoidal, and beyond which, further to the right, the waves would get flatter and longer. This represented the beginning of a procession of waves advancing into still water. Then to the left of the original line separating the undulating and smooth water there would be associated with the rightward moving procession of sinusoidal waves the tail end of the leftward moving procession. This would give the end of a procession of waves.—Dr. **Ashworth** and Mr. Nelson **Annandale** gave an account of some aged specimens of sea-anemone (*Sagartia troglodytes*) which had been kept in an aquarium in Edinburgh for about fifty years. They are more sensitive than younger individuals to changes of environment, and slower in expanding when conditions again become favourable. They breed very sparingly, while the younger specimens from fourteen to fifteen years old kept in the same aquarium produce hundreds of young. There is only one other recorded case of longevity in cœlenterates, a specimen of the anemone *Actinia mesembryanthemum*, which died in 1887 at the age of about sixty-six. According to unpublished observations of Mr. J. S. Gardiner, the solitary coral *Flabellum rubrum* lives to the age of twenty-four years, while colonial corals, such as Goniastræa, Prionastræa, Orbicella, and Pocillopora, reach the age of twenty-two to twenty-eight years.—In a note on the effect of transverse magnetisation on the resistance of nickel wire at high temperatures, Prof. C. G. **Knott** described a curious result recently obtained. The effect of a strong transverse field is to diminish the resistance, and as the temperature rises the percentage change of resistance falls off very steadily until 280° C. is reached. It begins then to fall off more slowly, passes through a pronounced minimum at about 290°, rises to a sharp maximum at 320°, and then falls rapidly to zero at about 346°. A similar effect, but much less pronounced, is indicated in the author's last published paper on the effect of longitudinal magnetisation.—Mr. J. R. **Milne** exhibited his new design of juxtaposíter for bringing into contact two beams of light in spectrophotometry. The instrument had been made for him by Mr. Hilger, and consisted of a special form of glass prism by means of which two beams of light originally apart were brought accurately with their contiguous edges in contact, each beam having been subjected to exactly the same treatment in the prism. The device could also be adapted to certain forms of polarimeter.

DUBLIN.

Royal Dublin Society, June 21.—Prof. G. A. J. Cole in the chair.—A general method in qualitative analysis for determining the presence of an oxide: Prof. C. R. C. **Tichborne**. The author proposed to use the reaction of phenol-phthalein with acid-carbonate of sodium. Phenolphthalein is colourless in neutral solutions, red with alkaline carbonates, and colourless with acid-carbonates. Most metallic oxides will reduce a certain proportion of the acid-carbonate to the normal carbonate, and the solution then strikes a deep crimson colour if filtered from the oxide and tested with the phenolphthalein. Almost all hydrated oxides and oxides made in the moist way decompose the sodium acid-carbonate solution. Mineral oxides or oxides which have been ignited, with a few exceptions, behave badly in this respect. Ferric oxide and alumina do not act, as the carbonates do not exist. The following oxides will reduce the acid carbonate to the neutral salt of soda:—oxides of lead, silver, bismuth, zinc (ignited and precipitated), copper, antimony, cerium, iron (other than Fe_2O_3), mercury, and tin.—A method for the mechanical analysis of soils: T. **Crook**. The method described is a hydraulic one, and may be regarded as a modification of the Schöne process. No piezometer is used, and the speeds of flow are standardised by varying the size of the outflow aperture and the head of water. The scheme of analysis suggested is a fairly complete one, including the coarser ingredients, as well as the fine earth. The author urges that the object of a mechanical analysis should be twofold:—(1) to enable a moderately definite idea to be formed of the way in which a soil is built up in its natural state; (2) to show something of the physical properties possessed by the soil.—The state in which helium exists in pitchblende: R. J. **Moss**. When pitchblende is reduced to powder in a vacuum, water vapour, helium, carbon dioxide, nitrogen, and oxygen are liberated. Water is the chief substance set free; of the gases, helium sometimes constitutes about half. The helium obtained by rather coarse pulverisation was about 1 per cent. of the total quantity present in the mineral, as determined by fusion with hydrogen potassium sulphate. The carbon dioxide obtained mechanically was less than 1 part in 10,000 of the total quantity present. The results support the supposition that helium exists in pitchblende in the free state, and is contained in extremely minute cavities. A specimen of pitchblende, powdered *in vacuo*, yielded gases containing 0·7 per cent. of hydrogen, which may possibly be a product of the action of radium on the water contained in the cavities of the mineral.—The Rev. H. **O'Toole** exhibited and described an apparatus for determining the expansion of rods, &c., when heated.

PARIS.

Academy of Sciences, July 4.—M. Mascart in the chair.—On certain functional equations and on a class of algebraic surfaces: Émile **Picard**.—Syntheses in the anthracene series. Triphenylanthracene dihydride and its derivatives: A. **Haller** and A. **Guyot**. Two modes of synthesis are given, the one starting from diphenylanthrone and the other from triphenylmethane-*o*-carboxylic acid methyl ester, making use of the Grignard reaction. Both give good yields.—Muscular work and expenditure of energy in dynamic contraction, with gradual shortening of the muscles: A. **Chauveau**.—*Trypanroth* in the treatment of trypanosomiasis: A. **Laveran**. The use of this dye was proposed by Ehrlich and Shiga. The effects produced by this reagent are compared with those of arsenious acid; the two have also been tried in combination, but the general results are disappointing.—On the properties of different substances as regards their ponderable emanation: R. **Blondlot**.—On the seeds of Nevropteris: M. **Grand'Eury**.—Presentation of the fifteenth *Bulletin chronométrique* (1902–1903) of the Observatory of Besançon: M. **Lœwy**.—M. Fliche was elected a correspondant of the academy in the section of rural economy, in the place of M. Lechartier.—On functions representable analytically: H. **Lebesgue**.—On the general theory of networks and congruences: Émile **Martin**.—On a general equality common to all fundamental functions: W. **Stekloff**.—On the stability of aërostats: Henri **Hervé**. Comparative effects of the β-rays and the n-rays, as well as of the α-rays and the n_1-rays, on a phosphorescent surface: Jean **Becquerel**. The radiations emitted by polonium affect a phosphorescent calcium sulphide screen, the action differing according as the radiation has passed through glass or not.—On the kathode rays. A reply to the note of M. Pellat: P. **Villard**.—On the measurement of temperature: Ernest **Solvay**. If two portions of a substance situated near to each other have widely differing temperatures, it is impossible to measure this difference with a thermometer, and a possible case of this kind is given.—On the spectrophotometric estimation of small quantities of carbon monoxide in air: L. de **Saint-Martin**. The instrument measures the ratio between the amounts of hæmoglobin combined with oxygen and carbon monoxide, up to the limit of 1 per cent. of CO.—The determination of the atomic weight of nitrogen by the volumetric analysis of nitrogen monoxide: Adrien **Jacquerod** and St. **Bogdan**.

Pure nitrogen monoxide, prepared from sodium nitrite and hydroxylamine sulphate, was reduced to nitrogen by means of a red hot iron wire, and the change of pressure at constant volume measured. The value 14.019 is deduced from the preliminary experiments as the atomic weight of nitrogen.—Allotropic states of antimony sulphide and their heats of formation: MM. **Guinchant** and **Chrétien.**—The action of ammonia gas upon trichloride, tribromide, and triiodide of arsenic: C. **Hugot.** Arsenic trichloride reacts with ammonia at $-40°$ C., forming arsenic amide, $As(NH_2)_3$. This amide is insoluble in liquid ammonia, but is immediately decomposed by water. The same amide is formed from the bromide and iodide of arsenic. Kept at 0° C., the amide slowly loses ammonia and gives the imide, $As_2(NH)_3$, and this, heated to 250° C., gives the nitride, AsN.—On a method of splitting up fermentation lactic acid into its optically active components: E. **Jungfleisch.** The separation is based on the differences in properties of the three lactates of quinine, and full details of the method adopted are given. Syntheses of pentamethyleneglycol, of the nitrile, and of pimelic acid: J. L. **Hamonet.** The glycol has been obtained from the corresponding dibromopentane, by conversion into the diacetin, and this into the glycol. Pimelic nitrile was obtained from diiodopentane by heating in alcoholic solution with potassium cyanide.—The action of mixed organomagnesium compounds on phthalimide and phenylphthalimide: Constantin **Béis.**—Iodo compounds obtained from metanitraniline: P. **Brenans.**—New synthesis of αα-dimethyladipic acid: G. **Blanc.**—On atmospheric formaldehyde: H. **Henriet.** In a preceding note the amount of formaldehyde existing in the air is estimated to be from 2 to 6 grams per 100 cubic metres of air. M. Armand Gautier has now pointed out that air containing such a proportion of formaldehyde is absolutely irrespirable. The production of carbon dioxide by passing the air over mercuric oxide heated to 250° C. must therefore be attributed to some compound of this aldehyde.—On recent results in porcelain manufacture: F. **Garros.**—On the mechanism of the contraction of muscular fibres, and in particular those of the adductor muscles of lamellibranchs: F. **Marceau.**—On some points in the anatomy of cirripedes: A. **Gruvel.**—The culture of spermatozoids: Alphonse **Labbé.** It is possible for the spermatozoid to commence to develop by itself on a simple culture medium, and away from any organised substratum.—The colours of flowers: G. **Coutagne.**—The question of the cultivation of cotton in tropical Africa: Aug. **Chevalier.**—The presence of hydroquinone in the pear: G. **Rivière** and G. **Bailhache.**—On the lateral roots of the pepper plant: H. Jacob de **Cordemoy.**—New researches on the vegetative apparatus of certain Uredineæ: Jakob **Eriksson.**—On the culture and development of the fungus which produces anthracnosis in the vine: P. **Viala** and P. **Pacottet.**—On the variability of temperature in the Antarctic regions: Henryk **Arctowski.**

NEW SOUTH WALES.

Linnean Society, May 25.—Dr. T. Storie Dixson, president, in the chair.—The botany of south-western New South Wales: F. **Turner.** The characteristics of the indigenous and acclimatised vegetation of the country lying between 35° S. lat., and the Murray or Hume River (the boundary between New South Wales and Victoria), and 141° and 147° E. long., are discussed. The census of the phanerogams and vascular cryptogams now brought forward comprises a total of 379 genera and 949 species.—Studies on Australian Mollusca, part viii.: C. **Hedley.** In August, 1902, Mr. G. H. Halligan and the author made a single cast of the dredge in 100 fathoms, 16 miles east of Wollongong—a depth for the first time attained by local workers. The haul was very successful, and produced a large number of Mollusca. The new species largely duplicated those of the *Thetis* expedition, and were noted during the progress of the report thereon. Other species of interest are now discussed.—The bacterial origin of the gums of the arabin group, xi., the nutrition of *Bact. acaciae*: Dr. R. Greig **Smith.** *Bact. acaciae*, the arabin-former, produces gum readily in the presence of suitable nutrients. Levulose, saccharose, maltose, mannite, and glycerin are sources of carbon, while dextrose, galactose, lactose, and raffinose are not. Dextrose or galactose prevents the gum being formed from levulose or maltose. The organism acquires and readily loses the power of utilising saccharose. It temporarily loses the gum-forming faculty when subcultivated upon sugar-free media. The amides are the best nitrogenous nutrients; a trace of asparagine (0.04 per cent.) is sufficient to produce half the maximum amount of gum. Salts may accelerate, depress or prevent gum-formation. Traces of alkaline citrate or succinate were most favourable. Sumach tannin assists the formation of gum upon artificial agar media. Oak tannin hinders the formation, but the retarding effect may be neutralised by the addition of glycerin. The bacterium might be used to distinguish certain tannins. The tannin probably acts physically by making the medium more contractile, so that the bacteria are slowly supplied with nutrients in solution. The optimum temperature is 17° C. The most suitable medium, as deduced from the experiments, serves as a diagnostic for other gum bacteria. Gum acacia has not a cellulose origin. In the host plant it is formed from the wandering sugars, levulose and maltose. Manuring with saline matters does not promise to be a remedy for the prevention of gum-flux in fruit trees. Peach trees that were inoculated with *Bact. acaciae* (from *Acacia binervata*) developed gum-flux. The exudate was a metarabin gum. The host plant can convert *Bact. acaciae* into *Bact. metarabinum*, proving what had been suspected, that the latter is a variety of the former, producing an insoluble gum. This explains the uniformity of the gums from certain species of trees.—The loss of colour in red wines: Dr. R. Greig **Smith.** Two samples of dry red wine which had exhibited the phenomenon of "*vin tourné*" were found to contain acetic bacteria.

CONTENTS.

THURSDAY, JULY 21, 1904.

THE MIND OF A GREAT THINKER.

An Autobiography. By Herbert Spencer. Two volumes. Pp., vol. i., xii+556; vol. ii., ix+542. (London: Williams and Norgate, 1904.) Price 28s. net.

A GREAT and peculiar interest attaches to these volumes, because in them Herbert Spencer has displayed the steps of the evolution in his own mind of that great scheme of universal evolution which has so profoundly affected modern thought, and has described the mental characteristics that conduced to the conception and the working out of that scheme. Spencer was peculiarly well fitted for the task of self-revelation, and it may safely be said that never before have the mental processes by which a great thinker has produced a vast system of conceptions been so clearly exposed.

The exposition is scattered through more than a thousand pages of matter, much of which is trivial or redundant, and it is perhaps worth while to set down consecutively, and in what seems the order of relative importance, the peculiarities of the philosopher's mind and character which, according to his own account, played a principal part in making the synthetic philosophy just that which it is.

Spencer rightly claims that he possessed in an exceptional degree the three great faculties (1) of deductive synthesis; (2) of analysis, leading to the discovery in complex and seemingly widely different phenomena of the elements or features that they have in common, and so to the inductive verification of large deductions; (3) "the ability to discern inconspicuous analogies."

The first of these was conspicuously manifested at every stage of the development of the system, the earliest considerable display of it being the deduction from the "law of equal freedom" of the conclusions as to political and social institutions presented in "Social Statics." The second was early manifested in the famous essay on "The Universal Postulate," which aimed "to identify the common elements of all those beliefs . . . which we regard as having absolute validity." The third was brilliantly exercised in the discovery of that celebrated analogy which has now become incorporated in common speech in the phrase "the social organism."

These three powers were certainly present in very high degree, and the deductive and inductive tendencies preserved a balance such as is by no means common. But it is possible that many minds have equalled Spencer's in these respects, and the exceptional development of these powers would not have sufficed to give us the synthetic philosophy in the absence of certain other very strongly marked mental traits that contributed to render Spencer's mind peculiarly effective in the carrying out of the great work that he accomplished. Among these the first place must be assigned to the effective belief in universal causation according to immutable laws, a belief early acquired and constantly fostered by the questions put to young Spencer by his father, who rightly considered the leading to a search after causes to be the most important function of the educator. "A constant question with him was,—'I wonder what is the cause of so-and-so';—always the tendency in himself, and the tendency strengthened in me, was to regard everything as naturally caused." The "constitutional readiness to grasp the abstract necessity of causal relations" thus "rendered by practice unusually strong," Spencer himself seems to have regarded, probably rightly, as the most important feature of his intellectual equipment, just as the lack of development, and, in fact, the actual repression, of this tendency, strong in most children, was and still is the gravest defect of English education. Hardly less important was the supreme confidence in his own mental processes, amounting, indeed, to intellectual arrogance, which, at the age of twenty, rendered him desirous of making public "some of my ideas upon the state of the world and religion," and which, a much more exceptional fact, remained unimpaired throughout his long life. There can be no doubt that this was essential to his achievement; by the lack of such confidence many fine intellects are rendered sterile, and had Spencer not possessed it in a very remarkable degree, had he been ever so slightly infected with that diffidence which was so marked a trait of his friend, George Eliot, he would not even have embarked upon a literary career, or, if embarked, he must have remained comparatively unproductive.

Closely allied with this last, and still more closely allied with one another, were the three traits "disregard of authority," "the absence of moral fear," and the tendency to criticise rather than to appreciate, each carried to a very extraordinary pitch. These, generating a repugnance to every kind of statement based upon authority and not appealing to reason for its acceptance, seem to have determined the trend of intellectual activity from the earliest years, from the time when as a small boy Spencer refused to apply himself to the study of Latin or of other languages and at the age of thirteen years rejected the current definition of inertia, to the time when he set aside all religious authority, laid down Kant's "Critique of Pure Reason" rejecting his doctrine of time and space "at once and absolutely" after reading a few pages only, set himself in "Man *v.* the State" in unqualified opposition to the dominant trend of political change, and criticised adversely the frescoes of Michael Angelo in the Sistine Chapel, the compositions of Raphael and of Wagner, the dialogues of Plato and the architecture of Venice.

Important, too, was his persistency in the pursuit of any end, his "tendency . . . to be enslaved by a plan once formed," frequently displayed throughout life in things both large and small. Without this natural persistency he would not have gone far towards the completion of his great scheme in the face of serious pecuniary difficulties and in spite of disturbances of health which, whether they were serious or not, certainly diminished very greatly his capacity for work. In boyhood this persistency was displayed very remark-

ably when he walked from Hinton to Derby, a distance of more than one hundred miles, in three days almost without food or sleep, and its manifestation in later life is well illustrated by the statement that after the projection of the evolutionary system at the age of thirty-seven, "nearly everything I wrote had a bearing, direct or indirect, on the doctrine of evolution."

Among the characters of direct importance to his intellectual productiveness must be reckoned the freedom and spontaneity of his ideational processes. During boyhood trains of ideas were apt to occupy his attention for long periods excluding all awareness of his surroundings, and this seems to have been especially frequent during walking. He speaks of this free flow of ideas in boyhood as "castle-building," but names it "constructive imagination" when, in later life, owing to systematisation of interests, his ideational processes tended towards ends related to his general scheme of conceptions. This spontaneity of the ideational processes enabled him to reach his conceptions and conclusions with a minimum of voluntary effort and, indeed, his efforts were more often directed to the checking rather than, as with most of us, to the promoting of the flow of thought. The following passage describes this as well as another important mental trait.

"It has never been my way to set before myself a problem and puzzle out an answer. The conclusions at which I have from time to time arrived, have not been arrived at as solutions of questions raised; but have been arrived at unawares—each as the ultimate outcome of a body of thoughts which slowly grew from a germ. Some direct observation, or some fact met with in reading, would dwell with me: apparently because I had a sense of its significance. It was not that there arose a distinct consciousness of its general meaning; but rather that there was a kind of instinctive interest in those facts which have general meanings. For example, the detailed structure of this or that species of mammal . . . would leave little impression; but when I met with the statement that, almost without exception, mammals . . . have seven cervical vertebræ, this would strike me and be remembered as suggestive."

In this passage is indicated the last of the faculties of primary importance, the faculty of seizing upon facts or conceptions that were of significance for his scheme of thought, well illustrated by his adoption and extended application of von Baer's phrase "the change from homogeneity to heterogeneity." It was this subtle and ready working of selective attention that rendered unnecessary the storing in the memory of vast masses of facts, and enabled him to dispense with any very extensive reading. Spencer's "sporadic memory" was avowedly poor, and this fact, cooperating in youth with a constitutional idleness, a distaste for continued reading and an impatience of opinions with which he did not agree, and in later life cooperating with an incapacity for reading dating from the time of the writing of the "Psychology" (æt. 38), very effectively preserved him from that "accumulation of knowledge in excess of power to use it" which he deplored as one of the common results of the current educational methods and regarded as one of the principal sources of intellectual sterility in many able men. It is an interesting question, How would Spencer's work have been modified had he devoted much time and energy to reading in place of passing restlessly from place to place, unable to bear solitude, constantly seeking to kill time, as he tells us, by various trivial occupations? Would extensive reading have choked the springs of production? There can be no doubt that, had his mental digestion proved equal to the task, a greater acquaintance with the history of thought would have enabled him to raise his works to a still higher level than that they actually attained—to secure for them an even more solid and enduring fame.

Of the further qualities that especially contributed to determine the character of his political and ethical doctrines, we may note a love of freedom, a quick sympathetic resentment of all injustice, a high valuation of pleasure for its own sake.

As to the general impression of the man produced by this autobiography, it seems certain that it is unduly harsh and unfavourable, for Spencer persisted with almost painful honesty and in accordance with the principle he had adopted, in laying stress upon the distinctive or peculiar features, while neglecting those more amiable traits which he shared with men in general. The result is that, whereas most biographies, and even autobiographies, are of the nature of a portrait, in which the artist selects an aspect and idealises to some extent the features of the subject, this one resembles rather a harsh, crude photograph that reproduces with relentless accuracy, and even gives undue prominence to, the lines and the warts, all the asperities of nature and all the bruises of the battle of life.

W. McD.

AMERICAN BIG GAME.

Musk-Ox, Bison, Sheep, and Goat. By C. Whitney and others. American Sportsman's Library. Pp. 284; illustrated. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1904.) Price 8s. 6d. net.

The Still-Hunter. By T. S. Van Dyke. Pp. viii+390; illustrated. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1904.) Price 7s. 6d. net.

THE members of the deer tribe, together with the pronghorned antelope, or prongbuck, having been described in an earlier volume of the same series, the work standing first in our list completes the account of the wild ruminants of North America. The names of the authors—Mr. C. Whitney for the musk-ox, Mr. G. B. Grinnell for the bison, and Mr. O. Wister for the mountain sheep and the white goat—form a sufficient guarantee that the text of this volume will combine that mixture of sport and natural history for which the true sportsman always looks in works of this nature, and a glance at its pages shows that such is really the case. From title-page to index the method of treatment and the style of writing are admirable, so admirable, indeed, that there is scarcely a sentence to which exception can be taken.

One admirable feature is that all three authors have

agreed to adopt one system of nomenclature, selecting that of Mr. Rowland Ward's "Records of Great Game." Not only is this satisfactory from the point of view of uniformity, but it indicates, in some degree at any rate, a tendency to revolt against the American practice of regarding every colour-phase of an animal as representing a distinct species. Accordingly we find all the American forms of wild sheep included under a single specific heading. In the case of the musk-ox, the author has indeed seen fit to depart from this admirable practice, classing the East Greenland animal as a species apart from the typical *Ovibos moschatus* of the Barren Grounds. Moreover, he is not justified in suggesting that the name *O. m. wardi* (first proposed in our own columns) should give place to Dr. Allen's *O. pearyi*. Doubtless Lieut. Peary has more claim to have a musk-ox named after him than has Mr. Rowland Ward, but if we are to disregard the rule of priority in regard to names of recent origin, zoology will soon be in a state of hopeless chaos.

Since the history of the bison has been written and re-written over and over again, the portion of the present volume dealing with the musk-ox has greater claims to novelty than have the chapters devoted to the first-named animal. Mr. Whitney's account of the extreme difficulties and hardships inseparable from an expedition into the Barren Grounds shows that musk-ox hunting is by no means holiday work, and that even when plans have been most carefully laid, a trip may result in failure even to sight the game. Perhaps it is not generally known that previous to the author's venture the only extensive trips that had been made into the Barren Grounds were those of the two Englishmen, Mr. Warburton Pike and Mr. H. T. Munn.

As a companion to the preceding excellent volume and its fellow in the same series, "The Deer Family," Mr. Van Dyke's "The Still-Hunter" may be heartily commended. Written more exclusively from the sportsman's point of view, it deals in considerable detail with the technique of stalking—or "still-hunting" as our American friends term this kind of sport—and is especially devoted to the pursuit of the white-tailed and mule deer and the prongbuck. As we learn from a statement on the back of the title-page and the preface, this volume is a new and illustrated edition of a work which originally appeared so long ago as 1882 or thereabouts. But it is none the worse for this, since it not only describes American deer-stalking in its palmy days, but is thoroughly up to modern requirements in the matter of rifles and other essentials of sport.

The illustrations, which are both numerous and artistic, are nearly all drawn for a special purpose, and serve to indicate both the impediments and the facilities with which the sportsman is likely to meet in the pursuit of his quarry. While the earlier chapters are devoted to a description of the manner in which to recognise good hunting grounds, and the various methods of tracking and shooting deer, the later ones treat more especially of rifles and how to use them, with a discussion on the type of bullet and the charge of powder best suited to this kind of sport.

If the big-game sportsman who intends to shoot in America be provided with the volume heading this notice and its companion on the "Deer Family," together with Mr. Van Dyke's "Still-Hunter," he may consider that, so far as literature is concerned, he is thoroughly equipped for his task. The first two volumes have, in addition, no small amount of interest for naturalists of all countries. R. L.

THE ORBIT OF A PLANET.

Grundriss der theoretischen Astronomie und der Geschichte der Planetentheorien. Zweite vermehrte Auflage. By Prof. Johannes Frischauf. Pp. xv + 199. (Leipzig: Wilhelm Engelmann, 1903.)

THE title of this work is too comprehensive; an outline of theoretical astronomy might be expected to touch at least gravitational theory, even if other physical sections were omitted. Prof. Frischauf's work—the first edition of which appeared in 1871—is engaged almost exclusively with the geometrical problem of finding an orbit from observation, and with a detailed history of Kepler's search for the true form of a planet's orbit. It is intended as an introduction, and is not ambitious for completeness; indeed, it omits many things a student might well be told, which would not have broken its attractive readable quality. For example, there are many better approximations for solution of Kepler's problem than that given on p. 6, and the well known graphical solution with the help of the curve of sines is not mentioned; this should not be omitted, for it is a method of real utility, and with proper care can be worked, as Bauschinger says, with an error not exceeding a tenth of a degree.

The author is well advised in following Gauss closely; it is almost inevitable that the work should be largely composed of excerpts from the *Theoria Motus*, and a writer serves his readers best who does not disguise them. But the numerical examples would have gained by being less faithful. The practice of astronomers in their reductions has undergone very great changes, and justice is not done to it by a note such as that at the bottom of p. 74, where, in reference to certain places of the sun extracted by Gauss directly from the tables—von Zach's presumably—Prof. Frischauf explains that our procedure is now less primitive.

Those who prefer to read Gauss and Olbers in the original, or in the masterly handbooks of Watson or Oppolzer, will find plenty to interest them in the third part of this work. Under a title of the history of the planetary theory, Prof. Frischauf gives, along with a cursory account of the rest of the history, a most interesting detailed story of Kepler's successive efforts to obtain the true form of a planet's orbit. Prof. Frischauf remarks that there are few more interesting pieces in the history of science; yet very few authors have allowed themselves space to do it justice. Dr. Frischauf, as professor at Gratz, is the appropriate man to write upon Kepler, for Kepler himself was a lecturer on mathematics at Gratz, and there made his name as an astrologer. The penetration of the older theories deserves more recognition than it gets; it is but little known how

well true elliptic motion can be simulated by an eccentric circle *and* Ptolemy's equant. The equant is a point about which motion in the circle appears uniform. In elliptic motion it may be easily seen that the empty focus is approximately such a point. Using the equant, the maximum error in longitude is only one quarter the square of the eccentricity—8′ only for Mars, and for the other planets, except Mercury, less than 2′. But if any reader wants to know all the equant can possibly be made to do before it must be condemned, let him read this account of Kepler's efforts.

OUR BOOK SHELF.

The Fourth Dimension. By C. Howard Hinton, M.A. Pp. viii+247; with coloured frontispiece. (London: Swan Sonnenschein and Co., Ltd., 1904.) Price 4*s.* 6*d.*

A book bearing the present title may be reasonably expected to contain certain things. In the first place it should have a clear exposition of Descartes's applications of algebra to geometry, and conversely of geometry to algebra, the logical conclusion of which consists in the removal of all restrictions as to the conceivable number of dimensions of space. In the second place it should contain clear, concise, and exactly worded statements of the peculiar and distinctive geometrical properties which are characteristic of spaces of two, three, four, or more dimensions respectively. Among these peculiarities might be cited, as examples, the number of possible regular figures corresponding to the five regular polyhedra of three-dimensional space, the number of independent motions of a rigid body, the properties analogous to those of the shortest distance between two lines, the symmetry of crystals, and, in short, any results calculated to convince the reader that the study of space not only of four, but of *five, six*, and generally *n* dimensions leads to the discovery of geometrical theorems no less interesting than those of ordinary plane and solid geometry.

Now such things as these are either entirely absent from the book or else they are mixed up with such a mass of irrelevant and discursive matter as to render it often quite impossible to make out what the author is driving at. The notion of a fourth dimension is associated with the belief in a higher world with electricity and magnetism, with organic life, with logic and philosophy, with the nature of the human soul, and with a variety of other ideas only calculated to mislead the reader as to the real use of such inquiries. It is doubtful whether any tangible idea of the "eight cell" or any other four-dimensional figure can be gained by mere playing with coloured squares or cubes. The proper way to realise the nature of such figures is by studying their projections on pairs of coordinate planes, and four-dimensional space has the great advantage over three-dimensional in that any figure formed of points can be completely represented by projections on two sheets of paper, whereas for a three-dimensional figure one sheet is insufficient and two sheets are too much.

There is a certain class of individual, far too common in this country, who busies himself in pestering his mathematical friends with long and rambling letters on such questions as "What is the fourth dimension?" or "What is the ether?" Such people very rarely know anything about the three dimensions of the space they live in, but Mr. Hinton's book will, it is to be hoped, give them something to think about which will at least amuse them and keep them occupied. The great misfortune is that such books are believed by the general public to be descriptions by a mathematician of the work of other mathematicians. Consequently, mathematicians obtain a reputation for being unpractical which they certainly do not deserve.

The Hill Towns of Italy. By Egerton J. Williams, jun. Pp. xiv+398; with illustrations from photographs and map. (London: Smith, Elder and Co., 1904.) Price 10*s.* 6*d.* net.

The majority of English people who visit Italy confine their attention to large towns such as Florence, Rome, Naples and Venice. The mediæval towns of Etruria and Umbria constitute practically a *terra incognita* to the ordinary tourist. The author has done useful work in directing attention to a district full of historic associations, and the picturesque glimpses which he has given us both of towns and country may well tempt those who have the time and opportunity to go and visit the district themselves.

If there is one feature which lends itself to criticism, it is that a perusal of the book does not give one a mental picture so much of the towns themselves as of an American *traveler's* impressions of them. It is probably very hard for any writer to describe Italian life who has not spent several of his early years in Italy. So long as the writer confines himself to purely descriptive matter the facts are Italian enough, but where he endeavours to give colour to the scene, that colour hardly feels right. We may cite such sentences as "The exquisite grace and sweetness of the madonna hold the onlooker like a vise" (query *vice*); "One more ancient madonna greeted me as I passed out by the left aisle." It would also be interesting to know the author's authority for such spelling as Velathri and Thrasymene. Velitrae and Trasimene are certainly usual. Seeing, however, that the book was written as the result of only a sojourn of a spring and summer among the hill towns, we can but be surprised at the amount of interesting matter which it contains.

Our Mountain Garden. By Mrs. Theodore Thomas. Pp. 212. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1904.) Price 6*s.* 6*d.* net.

Suburban gardeners sometimes attempt, with less or more success, generally less, to establish a mountain in the back garden. The author of this book has adopted the converse plan of establishing a garden on a New Hampshire mountain side. In this little book she tells us how she did it, what patience she exercised, what disappointments she experienced, what ultimate success she achieved.

The story is well told, and it is obvious that the gardener was not only successful, but that she deserved to be.

Nevertheless, her sympathies seem rather to be with the birds and wild animals to which she acted as hostess than with the plants she used for decoration. She seems to have looked on the plants as so many cakes of colour, useful for producing effect, but to have ignored the mental refreshment which a more thorough study of their peculiarities and of their manners and customs would have afforded.

Her "practical hints" are excellent, and will be serviceable to those disposed to follow her example and make a garden for themselves according to their own notions.

The list of shrubs, flowers, and weeds cultivated is disfigured by an unusual number of printer's "weeds," though it is scarcely fair to the "compositors" to attribute to them errors for which the author ought to be held responsible. If the book should, as is very likely to be the case, appear in a second edition, it is to be hoped that this list will be revised by someone familiar with the names of plants and with the way in which they should be spelt.

Guide to the Analysis of Potable Spirits. By S. Archibald Vasey. Pp. ix + 87. (London: Baillière, Tindall and Cox, 1904.) Price 3*s*. 6*d*. net.

THE analysis of potable spirits has within recent time acquired increased importance on account of the attention now given by medical men and others to the characters of potable alcohol, and also on account of the action of inspectors under the Sale of Food and Drugs Acts in connection with the attempts which are being made by various local authorities throughout the country to put a stop to the misdescription of spirits. The Acts under which the Excise authorities work unfortunately contain no adequate definition of such articles as whisky and brandy, and this omission has undoubtedly facilitated the manufacture of factitious spirits. At the present time there is practically no official control over the sale of ardent spirits beyond ensuring to the customer, solely in the interest of the Revenue, that their alcoholic strength shall not be below a certain minimum. The Revenue authorities are not concerned to know whether what is called whisky is a pot-still or a patent still spirit, whether it is made from raw grain or malt, or whether it is old or new. To them it is a matter of little moment whether what is called brandy is genuine grape spirit, or whether it is a rectified spirit obtained from maize or potatoes, flavoured with so-called essence of brandy and coloured with caramel.

Those who trade in these things are, however, taking steps to ensure that purchasers who, in the words of the Act, are entitled to be supplied with articles "of the nature, substance and quality demanded," shall be served with genuine grape-spirit when they ask for "brandy," and the Sale of Food and Drugs Acts have been set in motion to secure this, and convictions under their provisions have already been obtained. Now that a decision of one of the higher courts has been given, confirming those of the courts below, the local authorities will doubtless continue to take action, and public analysts will probably be very busy with such cases. Mr. Vasey's book, therefore, appears at an opportune time, and may be recommended to the notice of all who are interested in the subject of differentiating spirits.

Forestry in the United Kingdom. By Prof. W. Schlich, F.R.S. Pp. 72. (London: Bradbury, Agnew and Co., Ltd., n.d.)

THIS book gives a very able exposition of the pressing need of extended and improved forestry in the United Kingdom. It deals with certain important points already discussed, as the author informs us, in lectures at various centres. Prof. Schlich sets forth a very strong case in favour of the better management of British woodlands. His arguments, supported by very convincing statistics, are such as should meet with the approval and support of all interested in the subject. The problem of how to utilise to the best advantage our enormous acreage of waste land is ably dealt with, and in our opinion settled by the author in chapter iii. This chapter contains a most interesting discussion on the conflicting interests of forests and game preserves; Prof. Schlich, however, shows how these may be reconciled. The chapter also contains numerous practical hints and yield tables showing the financial return to be expected from properly managed woods. We cannot close this notice without mentioning the excellent series of photographs illustrating the natural regeneration of beech, the production of high-class oak timber, and the proper density of spruce woods. The photographs have been judiciously chosen by the author, and included to show what result can be achieved when forests are treated in a rational and systematic manner.

Ready Reference Tables. Vol. i. Conversion Factors. Compiled by Carl Hering. Pp. xviii + 196. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1904.) Price 10*s*. 6*d*. net.

THIS is the first of a series of reference tables which Mr. Hering has in course of preparation, and which are intended to contain all the data most generally required by engineers and physicists. The author has aimed not only at making the tables handy for reference, but also at making them complete and accurate to a degree not usually attained by pocket books. Thus in the present volume the conversion factors are given to six or more significant figures, their reciprocals are given, and also seven-figure logarithms. This is a degree of accuracy which can be but rarely required, and in deference, we suppose, to the practical engineer, the author has added approximate fractional values; everyone, therefore, should be able to find what he wants. All the values have been most carefully re-calculated and checked from the various legal definitions, thus making the data authoritative. The value of the book as a standard for reference cannot be questioned; the arrangement is more open to criticism, and we cannot help thinking that the method of tabulation adopted, which is to arrange all the tables in order of the size of the quantities, results in an unnecessary amount of repetition. For example, the same factor is repeated five times (with a change only in the position of the decimal point) for converting respectively milligrams, centigrams, decigrams, grams, and kilograms into grains. If this is really desirable, it should be consistently followed out; yet one finds the grain expressed only in terms of the milligram, centigram, and gram, the decigram only in terms of the grain and gram, and not otherwise mentioned in the table. The result is that one hardly knows where to look for what one wants, which considerably detracts from the merits of a compilation excellent in all other respects.

M. S.

A Compendium of Chemistry (including General, Inorganic and Organic Chemistry). By Dr. Carl Arnold. Translated by John A. Mandel, Sc.D. Pp. xii + 627. (New York: Wiley and Sons; London: Chapman and Hall, Ltd., 1904.) Price 15*s*. net.

THIS kind of book is perhaps more common and more popular, therefore, in Germany than in this country. It is neither a text-book nor a book of reference, but something between the two. Its aim seems to be rather to refresh the memory, if the word refresh can be used in this connection, than to train the mind. It is, in fact, a *multum in parvo* of information, which a student who had worried out his principles and theories beforehand, and merely required to marshal his facts and ideas, might use with advantage.

For example, the whole of chemical theory, including physical chemistry, is served up in the first hundred pages in a series of small doses of concen-

trated extract. There is a capsule of chemical statics, of dynamics, of physical mixtures, of thermochemistry, of electrochemistry, &c. The same concentrated form of diet is continued throughout the volume unrelieved by any historical references or illustrations of apparatus.

There are numerous little inaccuracies, both of author and printer, which it would be well to correct in a future edition. J. B. C.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Residual Affinity.

SIR OLIVER LODGE and Prof. Frankland have indicated (pp. 176, 222) the way in which the electronic theory may afford an explanation of various chemical phenomena; notably so in the case of solutions: the apparent dissociation of the ions of the solute being a consequence of partial withdrawal of the bonds or electric charges uniting them, these bonds becoming occupied in connecting the ions with the molecules of the solvent, and dissociation into ions being thus a consequence of the chemical affinity of the dissolved substance for the solvent, instead of being a proof that no such thing as chemical combination exists in a solution.

I should like to point out that this view was developed by the writer nearly thirteen years ago in a paper entitled "The Theory of Residual Affinity as an Explanation of the Physical Nature of Solutions," which appeared in the *Berichte*, 1891 (pp. 3629–3447), and of which some account will be found in the last edition of Watts's "Dictionary of Chemistry" under the head of "Solutions," p. 495. The only difference in the explanation there given from that given by Sir Oliver and Prof. Frankland is that the atomic charges were spoken of as fluid charges surrounding the atoms instead of as Faraday bundles.

The view that the charge uniting atoms in a molecule is a variable quantity was developed by the writer at a still earlier date in a paper on atomic valency, read before the Chemical Society, December 3, 1885, but printed privately only; a further view was propounded in that communication that the bonds or charges of atoms of a different nature were not exactly equivalent to each other, and were not necessarily expressible by whole numbers. Such a view gives a somewhat striking explanation of many chemical facts which are otherwise difficult of explanation, but it is independent of the explanation of the nature of solutions given subsequently, and now put forward by Prof. Frankland, the basis of which is the mobility and divisibility of the atomic charges. SPENCER PICKERING.

Harpenden, July 10.

A Volatile Product from Radium.

IN the course of some recent experiments on the excited radio-activity from the radium emanation, some evidence has been obtained which points to the conclusion that the emanation X of radium at one stage of the changes which it undergoes after being deposited on a solid body is slightly volatile even at ordinary temperatures. The effect which gives rise to this conclusion was first noticed in some observations on the rate of decay of the part of the excited activity deposited on a plate of copper immersed for a short time in dilute hydrochloric acid, in which the activity from a platinum wire exposed for a time to the radium emanation had been dissolved. When the copper plate with its active deposit had been placed inside a testing vessel and removed after a few minutes, it was noticed that a temporary activity, in some cases equal in amount to one or two per cent. of the activity of the plate, was excited on the walls of the vessel. This activity increased to about three times its original value in the course of thirty minutes after the removal of the active copper, and then decayed regularly to zero.

The amount of this radio-active deposit that can be obtained from a given amount of the direct radium excited seems to be increased by the solution and re-deposit of the emanation X, but it can also be observed from a wire just removed from the radium emanation. If the active wire is placed at once in the testing vessel without having had its temperature raised in any way and removed in a few minutes, an activity about 1/1000 of the whole activity shows itself on the walls of the vessel. The decay of the activity of this deposit is the same as that of the deposit obtained from the active copper. The following table gives the rate of change of the radiation from the walls of a vessel in which an active wire had been left for three minutes after its removal from the emanation:—

Time after removal in minutes ...	1	5	10	20	25	30	35	40	50	60
Activity	40	61	75	96	99	100	98	95	88	78

The active wire retains this power of exciting secondary activity for only a short time after removal from the emanation; after ten minutes the amount it excites is almost inappreciable. Merely washing the wire in a stream of running water and drying it over a gas flame, as is frequently done to prevent any trace of radium emanation clinging to the wire, increases the amount of the secondary activity to about 1/200 of the whole.

It is evident, then, that some sort of volatile product is given off from the active wire for a time which can excite an activity the rate of decay of which would indicate two changes in the active matter deposited, one producing rays and the other not giving rise to any radiation (E. Rutherford, "Radio-activity," p. 269). It is found that this volatile substance responds to none of the three tests for an emanation, it is not itself radio-active, it cannot pass without sensible loss through material substances such as paper and cotton-wool, and the activity due to it is not concentrated on the negative electrode in an electric field, but distributes itself evenly over all surfaces exposed to it.

The decay of the excited activity from the radium emanation has been explained by Prof. Rutherford on the assumption that there are three changes in the emanation X after its deposit on a solid body. In these three stages one-half the matter is changed in 3 minutes, 21 minutes, and 28 minutes respectively. In the first and third stages the change is accompanied by ionising rays, but the second is a rayless change. Now if it be supposed that after the first change has taken place the matter becomes slightly volatile, and some of it is concentrated on surrounding objects, a deposit would be obtained which would present the two remaining changes. From the equations for the radio-activity of such a deposit ("Radio-activity," p. 271), it is found that the radiation would increase for about 34 minutes, pass through a maximum, and then decay at the ordinary rate. This is very similar to the behaviour of the deposit obtained in the above experiments.

Curie and Danne (*Comptes rendus*, March 21) have obtained deposits showing similar characteristics by heating a radio-active wire within a cylinder and measuring the rate of decay of the activity of the cylinder. HARRIET BROOKS.

McGill University, Montreal, June 28.

The Traction of Carriages.

IT is a matter of general belief amongst drivers, owners, and builders of carriages that if the distance between the fore and hind wheels be increased so will the "draught" be heavier. I have put the following case before a builder: given two carriages weighing exactly the same, with the fore and hind wheels of each of the same height, but the body of one carriage much longer than that of the other, then the horse will have as much to do in the one case as in the other. The answer has been in more than one instance, the longer bodied carriage will be the heaviest to move. No reason has been given, nor can any explanation of the existence of this belief be offered. Can any of the readers of NATURE make any suggestion? E. WILLIAMS.

Ross, July 17.

UNIVERSITIES AND THE STATE.

THE deputation which was received by the Prime Minister on Friday last put forward a plea for the State endowment of universities which has been accepted by leading nations as a fundamental principle of progress. The influence of this principle upon the development of nations was shown by Sir Norman Lockyer in his address to the British Association last year, and the deputation was organised by the Association as the natural outcome of this address.

It would scarcely have been possible for a case to have received more impressive support than was given to it by the representatives of universities, industries, national and local interests who responded to the appeal issued by the British Association as to the need for recognition of the responsibility of the State for higher education and research. Of the four hundred people who expressed the sympathy of the bodies or organisations they represented with the manifesto sent out by the Association, only two hundred could be received by the Prime Minister, but these included leaders in many departments of national activity.

In introducing the deputation, the importance of the State endowment of universities was urged by Sir Norman Lockyer, as presented in his address. That university authorities hold the same view as the men of science and political leaders was shown by Prof. Pelham, representing Oxford; the Vice-Chancellor of Cambridge; and Mr. Chamberlain, who spoke for the new universities. The importance of applications of science was represented by Sir W. H. White and Sir W. Ramsay; the importance of the humanities by Sir R. Jebb; and the importance of research by Sir Henry Roscoe. Mr. A. Moseley spoke on American science and industry, and Mr. Bell, M.P., speaking in the absence of Mr. Burt, M.P., pointed out the importance of the reduction of fees and complete educational organisation, and showed by his presence that the State endowment of universities is approved by the artisan classes of the country.

In replying to the deputation, Mr. Balfour acknowledged that the endowment of universities assisted a nation in the industrial struggle, and that there is a great need, both in the new and the old universities, for help toward this object. The Chancellor of the Exchequer said that he would double the grant for university colleges this year, and he hoped to be able to redouble it next year; but before considering any larger contributions to university education he would like an exposition from the universities themselves as to the extent they were prepared to come under control if they received grants. He referred to the additional grant of 75,000*l*. a year to university colleges (representing a capital sum of 3,000,000*l*. at $2\frac{1}{2}$ per cent.) as having already been given as the result of the appeal made last year by the president of the British Association. From this it seems quite clear that if the university colleges had been content to wait until the general appeal was made, the result might have been better all round—so far as the early grant of money is concerned.

As the general result of the deputation, we may therefore take it that the principle of State endowment of universities has been conceded, and that the Government is prepared to deal with the question in a liberal manner when the universities have expressed their views as to control, and the finances of the country permit large contributions to be made.

The manifesto issued by the British Association was as follows:—

Statement prepared by the president of the British Association and revised by a committee consisting of the Deputy Vice-Chancellor of the University of Oxford, the Vice-Chancellor of the University of Cambridge, Sir Oliver Lodge, principal of the University of Birmingham, Sir Michael Foster, M.P., and Sir Henry Roscoe.

THE NATIONAL NEED OF THE STATE ENDOWMENT OF UNIVERSITIES.

(1) The British Association has taken action regarding the State endowment of universities, because at the present juncture the highest education and research is a matter not merely of academic but of the gravest national concern.

There is now a general opinion that Britain is in danger of falling behind in the industrial competition now going on between the most highly civilised States.

The university no less than the primary school is in question, because we are in the midst of a struggle in which science and brains take the place of swords and sinews; the school, the university, the laboratory and the workshop are the battlefields of this new struggle, and the scientific spirit must not be limited to the workshop, since other nations utilise it in all branches of their administration and executive.

The more our legislators, administrators and executive officers possess the scientific spirit, and the more the rule of thumb is replaced by scientific methods, the more able shall we be to compete successfully with other countries along all lines of national as well as of commercial activity.

It is a question of an important change of front, of finding a new basis of stability for the Empire in face of new conditions; and since the full life of a nation with a constantly increasing complexity, not only of industrial but of high national aims, depends upon the universal presence of the scientific spirit, of brain-power, our whole national life is involved.

The Function of a University in a Modern State.

The men upon whom the nation must chiefly depend for aid under the complex conditions of the modern world must not be entirely untrained in the study of the nature and causes of the things which surround them, or of the forces which have to be utilised in our daily life; their training and education in humanities must also have been of the widest.

Such men cannot be produced either by a university which neglects science or by a technical college which neglects the humanities.

Hence the universities must be enabled to combine these two sides of a complete education, and they must also be enabled to foster research along both lines, for research is the highest and most important instrument of education, as well as its most valuable result. When science and its applications were of less importance than now the humanities sufficed and university requirements were small; rooms, books, and a small number of teachers of a small number of subjects comprised the essentials of the university. Modern university needs have been too much regarded from this old standpoint.

All this is now changed. For instance, in the most modern German university the buildings, all elaborate and all differing from each other, have already cost a million, and still the university is not complete. Books have to be supplemented by expensive instrumental equipments, which constantly have to be added to or replaced, and by utilising this new material the fruitful ramifications of learning have increased fifty-fold, and the teachers naturally in even greater proportion.

The extraordinary thing is not that a claim to meet

these new conditions is made now, but that we have waited so long for it in this country while other countries faced them long ago.

The Money.

Money is required at the present moment for:—

(1) Buildings and equipments for pure and applied science in both old and new universities.

(2) Pay and pensions of an increased number of professors, demonstrators, &c., in pure and applied science in both old and new universities.

(3) Strengthening of science teaching and research in all, and of the humanities in the new universities.

(4) Reduction of fees, and the wide educational enfranchisement of proved ability in all classes.

Hitherto universities have looked mainly to private endowments. Universities have been regarded too much as luxuries of the rich, and perhaps on this ground higher education has been treated by the Government as of trivial importance to the nation, as a thing it may properly disregard.

Judging from the action taken in other countries, it is safe to say that private endowment has not produced more than 10 per cent. of the money actually needed in Britain.

Nor can we rightly appeal to local rate-aid alone. It would be unjust to expect certain restricted localities to provide universities which, if we are to go on, must be utilised by the whole Empire.

We are driven then to the State. The other civilised States largely endow their universities; Germany, with an aggregate income less than ours, spends roughly a million a year on its universities. The University of Berlin alone received more than 168,000*l.* from the State in the year 1891–2. In the United States, in addition to 200,000*l.* a year received from the Government, the States supply 700,000*l.* in the aggregate and private endowment 2,000,000*l.* The University of Tokio receives 130,000*l.* a year from the Government of Japan.

These figures derive their chief importance from the fact that these magnificently endowed and State-aided universities are the institutions we are contending with in the production of men to do the nation's work along all the lines of its activities.

But the large sums available for the efficient working of the German and American universities are not alone in question. The number of universities in Germany is nearly double that of the British universities. The number of first-class universities in the United States, where, as Mr. Choate has told us, education is the chief business of the nation, is nearly four times that of the British universities.

Can we Afford to Spend Money on Universities?

Britain's great needs at the present moment are brain-power to invigorate our commerce, among other things, and sea-power to guard it, among other things. The State has recently spent 120,000,000*l.* to bring our Navy up to date; it has not yet spent a single million on our universities.

Sir Robert Giffen has stated that the yearly income of the people of the United Kingdom may be taken as not less than 1650 millions, and their aggregate expenditure a few years ago was not less than 1,400,000,000*l.*, including 30,000,000*l.* for education, which is less than 2 per cent. of the whole. The amount borne on the estimates for education is about 13,000,000*l.*

He writes:—"The country should be spending 100 millions where it now spends 30, or about 5 per cent. . . . Such sums are not really extravagant. Extensive diffusion of education and scientific knowledge and training are not only essential to the greater efficiency of labour and capital by which the means of living are provided, but they are equally needed for the conduct of life itself, for the health and comfort of the workers."

It cannot be doubted that the expenditure will be quickly remunerative. More efficient workers will produce more.

Money so spent is seed from which a harvest can be looked for; the plentifulness of the crop will depend upon the seed and the way it is sown.

One of our manufacturers who has been most successful in applying science to industry has stated that if we were now to borrow 10,000,000*l.* for university purposes we should get the money back in the course of one generation a hundred-fold.

The recent recognition of the fact that we have too few universities, and that those that we have are inefficient for want of funds, is similar to that awakening which occurred in 1888 regarding the Navy. In both cases we have to correct past mistakes lasting for years, and seeing that university buildings, as well as annual endowments, are required, some special provision should be made for their early erection.

The Universities in Relation to Secondary Education.

Now that the primary and secondary schools throughout the country are being coordinated, the time has arrived for making our universities and university colleges efficient. The teaching connected with the universities must be of the highest, and the chief function of the secondary schools should be to produce students possessing that general training in science and the humanities which will ensure the success of their subsequent careers, either inside or outside a university.

A system of leaving certificates and a reduction of fees would at once get rid of the tyranny of merely qualifying or selecting examinations which are the bane of education, and would enable the training of the poorest to be carried to the highest rung of an unbroken ladder.

The deputation which advocated these views included representatives from the universities and university colleges, and from county, municipal and other educational authorities in Great Britain and Ireland, Canada and Australia. The list of the deputation contained the names of some who intended to be present, but were prevented from attending. Lord Rosebery, for instance, was unable to attend as Chancellor of the University of London; but with the exception of Oxford, Cambridge, and London, the chancellors of all the universities appear to have formed part of the deputation. A very large number of members of Parliament were present; and it is not too much to say that every important body of opinion—social, industrial, and intellectual—was represented. Among the members of the deputation were the following:—

The Vice-Chancellor of Oxford University, the president of Magdalen College, the president of Trinity College, Prof. Poulton, Prof. Miers. The Vice-Chancellor of Cambridge University, Sir R. C. Jebb, M.P., Mr. A. E. Shipley, F.R.S., and Prof. Forsyth, F.R.S.

The Vice-Chancellor (Dr. Pye-Smith) of London University, Sir Edward Busk, Sir Arthur Rücker, Sir Henry Roscoe, and Prof. Unwin. Sir John Aird, Bart., M.P., Sir G. C. T. Bartley, K.C.B., M.P., Sir M. M. Bhownaggree, M.P., Lord Hugh Cecil, Mr. W. R. Cremer, M.P., Sir M. Foster, K.C.B., M.P., Mr. Ernest Gray, M.P., and Dr. T. J. Macnamara, M.P. The chairman of the London County Council, and the chairman of the Education Committee of the L.C.C. Masters and wardens of the Fishmongers', Goldsmiths', Skinners',

Merchant Taylors', Ironmongers', and Vintners' Companies. Lord Reay, Hon. W. F. D. Smith, M.P., Lord Edmond Fitzmaurice, M.P., Sir William Hart Dyke, M.P., Mr. James Bryce, M.P., Sir Donald Currie, and Lord Stanley of Alderley. The principal of University College (Dr. Carey Foster), the principal of King's College (Dr. Headlam), Lord Macnaghten, the Bishop of London, the Bishop of Rochester, Sir John Wolfe-Barry, K.C.B., F.R.S., Mr. A. H. D. Acland, and Mrs. James Bryce.

Durham University was represented by Lord Londonderry, Earl Percy, the Bishop of Durham, the Dean of Durham, Principal Gurney, Lord Armstrong, Hon. C. A. Parsons, F.R.S., and Sir E. Grey, Bart.

The Chancellor of Victoria University, Manchester (Earl Spencer, K.G.), the Lord Mayor of Manchester, Sir J. T. Hibbert, K.C.B., Sir William Houldsworth, Bart., M.P., Sir James Fergusson, Bart., M.P., Sir J. Hoy, Sir Frank Forbes Adam, Prof. Schuster, Prof. Dixon.

The Chancellor of Leeds University (Marquis of Ripon, K.G.), Lord Wenlock, chairman East Riding Council; Mr. Herbert Gladstone, M.P.

The Chancellor of Liverpool University (Earl of Derby, K.G.), Prof. Boyce, F.R.S., Sir J. T. Brunner, Bart., M.P.

The Chancellor of Birmingham University (Mr. Chamberlain), Sir Oliver Lodge, Sir A. Hickman, M.P., Lord Cecil Manners, M.P., Sir P. A. Muntz, M.P.

The Bishop of Hereford, president of University College, Bristol; Prof. C. Lloyd Morgan, F.R.S., the Right Hon. Lewis Fry, Sir Frederick Wills, Bart., M.P., and Mr. C. E. Hobhouse, M.P. Alderman J. Bright, J.P., chairman of council of University College, Nottingham; Lord Henry Bentinck, M.P., and Sir F. A. Milner, M.P. Mr. J. H. Benyon, president of University College, Reading. The Duke of Norfolk, K.G., president of University College, Sheffield; Sir Fredk. Mappin, Bart., M.P., Dr. Hicks, F.R.S., Sir W. H. Holland, M.P., and Sir Howard Vincent, M.P. The Duke of Wellington, K.G., president of Hartley University College, Southampton; and Lord Northbrook, chairman Hampshire County Council.

The Head Masters' Conference, Rev. Dr. Gow. The Head Masters' Association, Canon Bell, Dr. McClure. The Assistant Masters' Association, the chairman, Mr. G. F. Daniell; vice-chairman, Mr. R. F. Cholmeley; and others.

The British Association for the Advancement of Science, the president, Sir Norman Lockyer, K.C.B., and the treasurer. The Royal Academy of Arts, the president, Sir Edward Poynter, R.A. The Society of Arts, Sir W. de W. Abney, K.C.B., F.R.S. Institution of Civil Engineers, Sir William H. White, K.C.B., F.R.S. Iron and Steel Institute, the president. The Society of Chemical Industry, Sir William Ramsay, K.C.B., F.R.S. Associated Chambers of Commerce, the president. Association of Municipal Corporations, Sir Albert Rollit, M.P. County Councils Association, Sir John T. Hibbert, K.C.B.

The Vice-Chancellor of the University of Wales (Principal Griffiths, F.R.S.), Lord Rendel, Sir Lewis Morris, the Right Hon. Lord Kenyon, Prof. R. W. Phillips, Prof. W. Rhys Roberts, the Lord Lieutenants of many counties, the Right Rev. the Lord Bishop of Llandaff, the Right Rev. the Lord Bishop of St. David's, and the president of the Miners' Federation.

The principal of the University of St. Andrews (Dr. James Donaldson), the president of University College, Dundee (Earl of Camperdown), and Sir John Long, M.P. University of Glasgow, Prof. G. G. Ramsay, Prof. Thomas McCall Anderson, Sir John Stirling Maxwell, Bart., M.P., Sir Herbert E. Maxwell, Bart., M.P. University of Aberdeen, Sir George King, K.C.I.E., F.R.S. University of Edinburgh, the Vice-Chancellor and principal, Sir William Turner, K.C.B.

The Vice-Chancellor of the Royal University of Ireland (Right Rev. Monsignor Molloy). The president of Queen's College, Belfast (Dr. Hamilton), the Lord Mayor of Belfast. The president of Queen's College, Cork (Sir Rowland Blennerhassett, Bart.). The president of Queen's College, Galway (Dr. Alex. Anderson). The president of University College, Dublin, Catholic University of Dublin (Rev. W. Delany, S.J.).

Principal Petersen, the McGill University, Montreal. Prof. A. Liversidge, University of Sydney.

Limitations of space will not permit the publication of a complete report in these columns, but the subjoined extracts from the speeches will convey an idea of the points raised. After the deputation had been briefly introduced by Sir Norman Lockyer, Prof. Pelham, speaking on behalf of the Hebdomadal Council of the University of Oxford, said:—

We are here to express our entire sympathy with the main object of this deputation. The older universities welcome this opportunity of standing in line with the newer universities which are growing up around us.

The Vice-Chancellor of the University of Cambridge (Dr. Chase) said:—

The council of the Senate of the University of Cambridge is deeply conscious, as, indeed, everyone must be who looks thoughtfully on the events of the time, how much that higher culture and that thorough scientific study and research which it is the province of a university to promote are needed for the service of the English nation.

It appears to us that the universities, in view of the increasing work which they are doing on behalf of the nation, are justified in asking for the sympathy and the cooperation of the State. We heartily join in the prayer that the Government would be pleased to regard the work of universities as of supreme national and imperial importance, and to give such aid as the several universities need and as wider considerations of national finance render possible.

Mr. Chamberlain, as Chancellor of the University of Birmingham, speaking on behalf of the new universities, said:—

Let me take Birmingham as an example and as a parallel to what is being done in Liverpool, Manchester, Wales, and Leeds. We have had to prepare the plan of a new scientific university, to deal only with that side of our work, at an estimated cost of 1,000,000*l.* sterling. Even then we shall not have fulfilled all our objects, for there will be many branches of higher scientific and practical education for which we have made no sufficient provision. In the case of Birmingham local subscription has produced about 450,000*l.*, and on the basis of that subscription we have put in hand what will amount to little more than one-third of the university requirements. We have called in aid the local rates, and the three counties of which Birmingham is the centre each contribute the sum of 500*l.* a year, and the corporation of the City of Birmingham has offered in aid a rate of $\frac{1}{2}d.$ in the pound, which will produce something between 6000*l.* and 7000*l.* per annum. Now, whatever may have been done, it is not enough, and we recognise that by our own unassisted resources alone we cannot provide the kind of education we believe the country requires. Already the State pays something like 13,000,000*l.* a year for primary education. Only a few thousands a year are found for the higher education to which we have learned to attach so great a value. I am not speaking merely as a Chancellor, but I have had some practical experience of the advantage which every statesman finds in discovering sources from which funds may be provided for all the admirable objects brought to his notice, and I do not press on you any particular figure or method of dealing with the important matter we have brought before you, but I hope we may have some crumbs from your table. I hope at least the present Government may be able to make a satisfactory beginning in recognising these new necessities. Possibly that beginning may not be wholly satisfactory to us, but we shall be always ready to take half a loaf until the time comes when we can get the whole, and I believe the initiation of such a policy on the part of any Government will be one of its best claims to the gratitude of the people of this country.

Sir William White, K.C.B., F.R.S., speaking as president of the Institution of Civil Engineers, and

as a representative of all branches of engineering, said:—

During the past year a committee representing all branches of engineering, and nominated by all the principal engineering societies of the country, has been considering the best system of training for engineers. Its work is still incomplete, but its investigations make it obvious that great extensions of existing universities and university colleges which provide for engineering education are needed in order to meet national requirements and to secure equality of conditions with those existing in other countries where industrial enterprise is making great strides.

British engineers consider that private enterprise and generosity should continue to play a leading part in the support of institutions for teaching the higher branches of their profession, but they hold that, in view of what is being done abroad, it is absolutely necessary that private efforts should be supplemented by substantial Government aid. Such a course on the part of the Government would undoubtedly tend to stimulate private generosity, and before long would place this country in a position of relative efficiency greatly superior to that which now prevails. With the rapid development of engineering now taking place in all directions, there is an absolute necessity for scientific procedure and a thorough knowledge of principles on the part of those employed therein. Unless immediate steps are taken to remedy needs that are universally recognised, the industrial position of this country must become increasingly unsatisfactory.

The importance of the application of science was urged by Sir William Ramsay, K.C.B., who, in the course of his remarks, said:—

In asking for a new departure—the State endowment of universities—we must inquire what information we can obtain from others who have previously made experiments. We find that on the Continent successful experiments have been made for many years. In these practical researches Germany has taken the lead; but in all European countries, and in America, progress is being made on lines closely resembling those which have been found advantageous in Germany. We may note that almost all the proprietors of chemical works, or of works which depend for their success on the application of chemical principles, are either university men who have taken a degree in science or men from "Polytechnika," who have taken a diploma.

One reason for the almost universal spread of university education is the very small fees that are charged to students. By far the larger portion of the cost of university education is paid by the State—probably three-quarters. Ten pounds covers a year's education in fees, whereas forty pounds must be charged here in non-endowed universities.

This close contact between science and industry can be maintained only by a graduated and relatively high scale of pay for the professors in the large universities. Unless the prizes are sufficient to tempt men to choose a scholastic career instead of a commercial one, the ablest young men will choose commerce.

In America most of the chemists have either been educated in Germany—the older generation especially—or have been trained in copies of the German schools of chemistry. Hence America entertains much the same ideas as Germany as regards the importance of scientific training. Indeed, manufacturers engage the services of youths who have not finished their "college" career.

As regards the merits of universities and "Polytechnika," the main difference is that in the former students have been trained in methods of research, whereas in the latter they have been taught what is already known. I am informed by a leading German manufacturer that he prefers the university youths to those trained in "Polytechnika," because the former are more suggestive. The inventive power is recognised as the highest and most lucrative when applied to industry. I am convinced that the bestowing of money on the support of the university teaching of science, while desirable for its own sake, will be like casting bread upon the waters, it will be repaid a hundred-fold.

In referring to the needs of the younger universities in respect to literary studies, Sir Richard Jebb, M.P., remarked:—

It would be a serious national misfortune if our education should become one-sided. The humane studies—history, philosophy, language, literature—cultivate the imagination, enlarge the sympathies, widen the outlook upon life, aid in fitting people to understand one another and to cooperate intelligently; in a word, they are essential elements in the formation of the efficient worker, whatever his line of work may be. That cardinal fact is thoroughly well understood in those countries where education, from the lowest to the highest grade, is best organised. Let us see to it that in our own country we do not overlook this fact. The men of science go heartily, I believe, with the men of letters in desiring that it should not be overlooked. The importance of maintaining such an equipoise in education might be urged on the utilitarian ground, as a condition of our holding our own in the competitions of the civilised world. But it must be urged also on a higher ground, as a thing essential to the intellectual and spiritual well-being of the nation and of the Empire.

Sir Henry Roscoe pointed out the influence of scientific research on our national well-being; and in his speech he said:—

It is to the university that we must mainly look to raise the type of man who by training and character is fitted to prosecute research. Are our British universities at the present moment adequately equipped in men and material to enable them to carry out successfully this national work? A comparison of their capabilities with those of other countries shows a deplorable deficiency in both the above respects.

This state of things being generally admitted, we come before you as the head of the Government to ask you to bring about that closer connection between scientific method, scientific studies, and national industry, upon which you have so strongly insisted, by giving to our universities a State endowment which will not merely serve as a national insurance against attack from without, but is, unlike others, a productive insurance which will repay the nation, not merely once, but over and over again.

Speaking more especially as a business man who has noted the effect of applied science in the industrial world, Mr. A. Moseley, C.B., remarked:—

I am practically impressed with the necessity for those in training for commerce and industry to be thoroughly equipped with technical instruction of university rank, designed to bear especially upon the particular vocations that the rising generation intend entering. On the points mentioned we are distinctly behind both Germany and the United States of America. The success of the United States at present, and perhaps even more so in the future, is and will be due to the higher scientific and practical training her young people receive in her universities first and technical colleges afterwards.

Mr. Bell, M.P., speaking in the absence of Mr. Burt as the representative of artisan classes of the country, said:—

This question is one of vital importance. Unfortunately, my practical knowledge of universities is little. But hitherto a university training has been the luxury of the comparatively well-to-do. The aim is to open the door to the choicer spirits of the poorer classes.

Lord Kelvin wrote to the president of the British Association expressing his regret at not being able to be present and his hearty wishes for the success of "every effort for the much-needed improvement and strengthening of the universities of the United Kingdom."

In the course of his reply to the deputation, Mr. Balfour said:—

I do not suppose that there have ever before been congregated in one chamber so many representatives of learning in this country. We have been told that we have fallen far behind at least two great countries in our educational

facilities. But I do absolutely deny that there is the smallest sign that in the production of these germinating ideas of science we have shown any inferiority, either to our relations across the Atlantic or to Germany, which I may remind the assembly has for many generations pursued this State-endowing process of applying science to industry. That we are behind Germany in that way I do not deny. Germany had a technical university, or gave technical teaching, I think, as far back—I am refreshing my memory—as the end of the eighteenth century, if not before. Of course, the general system of thought in Germany, the habits of the people and the Government in this respect places them at a great advantage as compared with us as far as the endowment of universities can help a nation, as I doubt not it can, in the industrial struggle. But my point is that mere endowment of universities will not, I think, add greatly to the output of original work of the first quality. What, then, will it do? It will do, or may help to do, what is, perhaps, now more important. It will provide an education which will render fit for industrial work all persons who, without university education, would be very ill equipped indeed. I concur with all the speakers to-day that there is a great need—a great financial need—both in the new and the old universities for help towards this object. But I would beg to point out that there is even a greater necessity than a well equipped university—that is, that capitalists should be prepared to realise what we realise in this room—the necessity of giving employment to those whom these universities are to turn out. I was much struck by an observation of Sir William White's. He pointed out that we possess most of the ships of the world—that we are the largest shipbuilders in the world—and yet he said that Germany has an incomparably larger number of students, far better machinery for educating these students, and more men occupied in the shipbuilding yards; and what Germany has done the United States are doing. One of two things is clear. Either our shipbuilders think this qualified class is necessary or they do not think so; or else they find British students, even though turned out in smaller quantities, are sufficient for their purpose, or they employ American and German students for their works. Are our manufacturers convinced that they get a better man if they get one who has been to a university? Or do they think that if a young fellow wants to become one of the captains of industry he should begin early in life? I think there is some evidence to show that they prefer the older course; and I should suggest they are wrong; and if they are wrong you must convince them they are wrong, otherwise there will be no advantage in turning out qualified students, for they will be content to use the man who acquires his training by actual day-to-day labour on the ship, but is not qualified by these higher scientific attainments which are more and more becoming necessary.

One other thing we want, and that, I think, is the creation of positions which will enable a man who has exceptional gifts of originality in science to devote his life to the subjects of his predilectinn so as not to be driven to another kind of life in which he will not be able to render the full service of which he is capable to his country. In Germany certainly—I am not sure about the United States—such positions exist to a far greater extent than in this country. In the main they must be attached to the universities. I cannot conceive any more admirable use of any funds which the universities can command than the increase of the number of such positions.

In the course of his remarks, the Chancellor of the Exchequer said:—

It would be of some assistance to those who may have to decide in future when money is available if the universities would consider to what extent they are willing to come under control if they receive grants, to what extent the State is to have a voice in fixing the fees of the students, to what extent it is to direct or influence the teaching, whether it is to allocate its assistance to promote special branches of study, or whether it is desired to make every university complete in itself. Some further exposition of their views would make it easier to deal with this question when the time comes for dealing with it.

THE MEETING-PLACE OF EAST AND WEST.[1]

THE publication of Dr. Stein's preliminary report to the Royal Geographical Society and of his own personal narrative of his explorations among the "sand-buried ruins of Khotan" is one of the most important archæological events of the year 1903. For the full scientific publication of the whole of his discoveries by the Indian Government we must perforce wait awhile, but we have all that is needed to enable us to form a general idea of them in the interesting and well published volume which lies before us.

Chinese Turkestan hardly sounds as if it were a land of very great interest, yet, as a matter of fact, it is historically one of the most interesting countries in the world. It is not a comfortable country: merely a string of oases half overwhelmed by a devouring desert of shifting sands, the great Taklamakan, and barred off from the rest of the world by huge and impassable mountains, scorchingly hot in summer and frozen by Arctic cold in winter. Yet these remote wilds have seen one of the most interesting phenomena of history, the meeting together of the civilisations of China, of India, and of Europe; here the antique culture of China had in the early days of the Roman Empire already been brought into contact with Græco-Roman civilisation, and we see the result of the meeting of the two, or, including India, three streams of civilisation in the mixed culture of Turkestan in the early centuries of the Christian era, which Dr. Stein has brought to light.

In those days Chinese Turkestan was the bridge between west and east; from west to east journeyed Roman merchants to buy the precious silk of Serica, and Persian ambassadors or fugitive princes passed seeking the assistance of the mighty Emperor of China; from east to west Chinese armies marched through Turkestan into the basins of the Oxus and Jaxartes, and even reached the Caspian, and Chinese pilgrims, like Fa-hien and Hiuen-Thsang, passed the fanes of Khotan on their way to the holy places of Buddhism in India; traffic to and fro was continuous, and the oases of the Taklamakan could maintain many famous cities, rich temples, and monasteries of renown.

In those days of her importance, as still in these of her desolation, eastern Turkestan was under the political hegemony of China. Legends, indeed, ascribe a remote date B.C. to the first entry of the Chinese into Kashgaria, but since real history (as apart from annals which have not yet been critically sifted) can hardly be said to begin for China before the reign of the great reformer Tsin Chi-Hwangti (B.C. 250), "the burner of the books," we are probably right in assigning the first Chinese occupation to the early days of the Han dynasty, under the emperor Han Wu-ti (B.C. 100), and its first real conquest to the famous General Panchao, who is said to have carried the Chinese arms as far west as the Caspian, and to have attempted to open up direct relations with the Romans (about A.D. 100). Henceforward Kashgaria remained nominally tributary to China; but though individual emperors asserted their authority in the far west from time to time, the country does not seem to have been regularly organised as a Chinese possession until the reign of the great Emperor Tai-tsong, the first monarch of the T'ang (A.D. 634). Under his equally powerful son Kao-tsong we find Chinese viceroys installed in Turkestan, who entered into regular relations with the peoples of the west. The last Sassanian King of Persia, Yazdijird, communicated with them, demanding Chinese assistance against the conquering warriors

[1] "Sand-buried Ruins of Khotan; Personal Narrative of a Journey of Archæological and Geographical Exploration in Chinese Turkestan." By M. Aurel Stein. Pp. x+503. (London: Hurst and Blackett Ltd., 1904.) Price 7s. 6d. net.

of Islâm, who were now overrunning his kingdom, but Kao-tsong refused to attack the Arabs. Firuz, a son of Yazdijird, fled to the Chinese court at Si-ngan-fu, and Kao-tsong proclaimed him King of Persia after the murder of Yazdijird. He was, however, never able to enter into possession of his kingdom, the Arab conquerors of which sent a formal embassy to the Chinese Emperor four years later (A.D. 655).

Thus Chinese Turkestan served as a bridge between east and west in the days of the great T'ang.

Since the period of the T'ang, Kashgaria has always remained nominally subject to China, and, despite the victory of the western religion of Muhammad over Buddhism, Chinese civilisation has always retained it in its *Kulturkreis*; the Chinese authority has always stood for order and for civilisation, and whenever, as in the years of independence under Yakûb Beg during the 'seventies of the nineteenth century, Islâm has succeeded in ousting the infidel rulers of the land, utter anarchy and barbarism has resulted. The defeat of the Muhammedans by the Chinese general Liu Kin-tang in 1878 was a victory for civilisation. To-day Chinese authority is more in evidence in Kashgaria and more firmly upheld than at any time since the days of the T'ang. The whole story of the retention of Kashgaria, not merely as an outpost of Chinese civilisation, but actually as a Chinese possession, throughout history, is an interesting testimony to the real civilised energy and organising power of the Chinese, as well as to their dogged persistence in pursuing their ends.

Chinese Turkestan is, then, a land of remarkable historical interest. Further, it is, like Egypt, a land in which archæological excavation would be likely to reap rich harvests, for here, as in Egypt, we have two factors which are of inestimable service in preserving the relics of the past intact—dryness and desert sand. The sand covers and protects, the dryness preserves. Hence it is that systematic excavations in the Egyptian manner, now for the first time essayed in Turkestan, have yielded such important results to Dr. Stein. Sven Hedin had already reported the existence of ancient remains in the Taklamakan, and Dr. Stein has explored and excavated them, bringing back with him an invaluable collection of relics of the early civilisation of this strange land, the bridge between west and east. His finds belong mainly to two distinctly marked periods, the third and eighth centuries A.D. The most important of the earlier sites is that in the desert north of Niya, away to the east of Khotan. Here was excavated a regular town of wooden buildings half buried in the sand, with the remains of the trees of its ancient orchards still standing around it. The date of the settlement is given by a document of the reign of the Emperor Tsin Wu-ti, of the Later Tsin (A.D. 265–290). Among the inhabitants Chinese officials were probably included, but the majority seems to have been of Indian origin. This is shown by the discovery of numbers of wooden tablets and parchments inscribed with Indian Kharoshthi writing. These are chiefly reports to the Indian rajas who governed the country. From this we see that the tradition of an Indian conquest of Kashgaria in remote days is founded on fact. That this Indian kingdom formed a road by which the culture of the west penetrated to the east there is no doubt. At Niya, indeed, has been found a striking confirmation of this; five hundred years after Alexander, we find in Turkestan an Indian letter sealed with a Chinese and with a Greek seal side by side! Greek intagli were in common request in this remote Chinese dependency, and the influence of the art of Gandhâra on that of Khotan is very evident from the numerous small objects collected by Dr. Stein on the site of Yotkan, the ancient representative of Khotan-town. The question as to how far Chinese art is really indebted, through the medium of Khotan and Gandhâra, to that of Greece has, apparently, yet to be worked out.

The other excavated sites are later in date. The miscellaneous antiquities from Yotkan partly bridge over the gap between the period of Niya and the period of Dandan-Uiliq, the most important of the later sites; and the great Rawak Stupa in the Yurung-kash district, which has yielded to Dr. Stein material of the most important kind for the history of early Buddhist art, belongs to the intermediate period. Ranged along the base of this *stupa* is a series of colossal stucco figures in alto-rilievo, representing Buddhas or Bodhisattvas (Fig. 1), and attendant Arhats, these last sometimes represented as grouped in the halo of a great Buddha. These remarkable examples of Buddhist art were mostly too bulky and delicate to be removed, and so were re-buried by the explorer after a complete series of photographs had been taken of them. Many of these are published as illustrations to chapter xxx. of Dr. Stein's book.

FIG. 1.—Rilievo Statue of Bodhisattva on South-west Wall, Rawak Stup Court. From "Sand-buried Ruins of Khotan."

Dandan-Uiliq is a site outwardly much resembling Niya, which Dr. Stein afterwards excavated, and has yielded, like Niya, many written records, but of course of later date and written in different languages and scripts. In some cases these are still of Indian origin. When the script is Brahmi, the language is sometimes Sanskrit, sometimes an unknown tongue, no doubt the native Indo-Scythic of Turkestan, the language of the *Yue-tchi*. The writing is usually upon paper, less usually on wood. The contents of the Brahmi documents are religious. Civil records, analogous to the Kharoshthi tablets of Niya, are chiefly Chinese. The settlement was, in fact, a Chinese Buddhist monastery,

and its ancient name was Hu-kwo. The Chinese documents date to the end of the eighth century, long after the Indian kingdom was extinct, and when the Chinese dominion, which had been triumphantly re-asserted by T'ang Tai-tsong, was seriously threatened by the inroads of the "Ta-Fan" or Tibetans. Actual Tibetan relics were discovered at Dandan-Uiliq.

Larger antiquities were also discovered here, chiefly Buddhist reliefs of stucco, and, more interesting still, frescoes which give us an unlooked-for insight into the art of Khotan at this period. Exhibited in the Chinese section of the British Museum is a remarkable fresco from Dandan-Uiliq, one of the most important of Dr. Stein's discoveries, representing two equestrian figures, with their costume most carefully depicted. This is not illustrated in Dr. Stein's book, and the omission is to be regretted, as the picture is one eminently calculated to interest the general reader for whose use the "Sand-buried Ruins of Khotan" is chiefly intended.

Another site, beyond Niya, at Endere, has yielded remains of the same date as those from Dandan-Uiliq. This place, Endere, is the most easterly point which Dr. Stein reached in his explorations. It is distant from Khotan some 250 miles, and from Kashgar no less than 550 miles. This fact alone gives some idea of the extent of ground which Dr. Stein covered in his rapid journeyings. His explorations were indeed carried out with remarkable energy, and their great success is the fitting reward of this energy and pluck. For it must be remembered that much of Dr. Stein's work was carried out in the intense cold of a Kashgarian winter, when the thermometer often fell to below zero Fahrenheit in the explorer's tent, when it was hardly possible to hold a pen for the cold, and even sleep was sometimes banished by its intensity. Under these extreme conditions Dandan-Uiliq and Niya were excavated. If we add to these rigours the difficulties of the journey from India over the Pamir passes, we gain some idea of what Dr. Stein has done. His mission has succeeded beyond his own most sanguine expectations, and the Indian Government has indeed served the cause of science well in sending him to Turkestan.
